An Address MEDICAL EDUCATION.

, , 0

Delivered at the Opening of the Medical Department of the Viotoria University of Manchester on Oct. 1st, 1909,

BY GEORGE R. MURRAY, M.A., M.D. CAMB., D.C.L., F.R.C.P. LOND.,

PROFESSOR OF SYSTEMATIC MEDICINE IN THE UNIVERSITY; PHYSICIAN TO THE MANCHESTER ROYAL INFIRMARY.

MR. VICE-CHANCELLOR, LADIES, AND GENTLEMEN, -The opening of a fresh winter session, marking as it does the commencement of a new academic year, is a fitting occasion on which not only to review the present state of medical education but also to endeavour to indicate the lines on which its future progress may be most efficiently developed. At the outset it is important to realise that no system of medical education, however good, can be permanent. The science and art of medicine are ever advancing, sometimes rapidly, sometimes slowly, and therefore from time to time our scheme of education must be readjusted to the requirements of the day so that our students may have the best equipment we can give them for the profession of their

To indicate the many ways in which this has occurred would require a review of the progress of medicine during the last 20 or 30 years, but a few illustrations will suffice to emphasise this point. Twenty years ago, when the tubercle bacillus had only recently been discovered, the examination of excretions for this micro-organism, as an aid to diagnosis, was regarded almost as a special investigation, whereas now every student is taught how to carry this out as part of his regular work in the hospital. The various instruments by means of which the blood pressure may be quickly ascertained at the bedside are yet more recent additions to our routine methods of investigating disease with which all now require to be familiar. Although students have not time to acquire the necessary technical knowledge to carry out X ray examinations, still it is essential that they should know what information can be obtained by the skilled use of this and other elaborate methods of clinical investigation and under what circumstances they may be profitably employed. Thus, although the principles of true education remain the same, their practical application to medical training must be re-adapted from time to time as fresh developments in medical science and practice take place. A course of medical education which fulfils our requirements to-day will not do so five or ten years hence, when we may confidently expect that still further stages of development in medicine will have been reached. Too frequent changes in the medical curriculum are not desirable, but it is evident that from time to time we should review our courses of instruction and methods of examination so as to bring them into line with recent but real and proved advances in knowledge. For this purpose it would be a great advantage to have occasionally a conference of medical teachers at which those engaged in teaching the various subjects included in the medical curriculum might meet to discuss the best methods of education and the true relationship of the different parts of the curriculum to each other. If such a conference were held every second or third year it would serve a useful purpose without taking up too much of our time. As it is, the teachers in the different universities and medical schools work more or less independently, whereas they might derive great advantage from a freer discussion of their experiences of different methods of teaching. It would doubtless add interest to the proceedings if some senior students and recent graduates could also, on suitable occasions, take part in the discussions As it is, many of us have derived great help and inspiration even from casual conversations with those who are engaged in teaching in the medical schools of this and other countries. The General Medical Council, of course, controls the general scheme of medical education and examination, but in the practical application of these principles to the special requirements of our medical schools such a meeting of teachers would be of much practical assistance.

In medicine old customs and usages die hard. In certain cases where they are good and still serve some useful purpose this is as it should be, but we are apt to cling to old empirical methods of practice and teaching long after the original reason for their adoption has passed away or has been found to be erroneous. Dr. Lusk, in a recent address, in order to illustrate this tendency, related the experience of an American officer who was visiting St. Petersburg. As he was being shown over the palace by a Russian officer he noticed a sentinel pacing up and down the middle of a courtyard, and inquired the reason of his being placed in such an unusual position. His companion did not know, but promised to find out. Investigation showed that 60 years before a little princess had found a snowdrop growing in the centre of this courtyard and had requested that it might be allowed to remain. Her father gave an order for a guard to be placed there to protect the flower. This order had never been rescinded, and so for 60 years a sentinel had paced up and down the centre of the

courtyard where the snowdrop had bloomed.

With the notable exception of Oxford and Cambridge, it is the usual custom in this country for a student to complete his curriculum at one medical school. Owing to the fact that these two universities are situated in comparatively small towns, the clinical subjects are generally studied in London or some other large medical centre. An interesting comparison was made by Sir Felix Semon in his address to the Manchester Medical Society between English and German medical education two years ago, in which he drew attention to the fact that in Germany a student is at liberty to migrate from one university to another. He may, if he wishes, change his university at the end of each half-year, and many students avail themselves of this liberty to the extent of visiting two or three universities in the course of their education. Owing to the relationship of the universities to the State this is easily done. It would be a decided advantage if in this country arrangements could be made so that a student of one university could, without incurring any additional expense, spend at least one of his five years at another. Perhaps in the future it may be possible for British, American, German, and French universities to interchange medical students with mutual advantage under some such arrangement as that which obtains in the case of the Rhodes scholars at Oxford. Our methods of education would also develop more rapidly if in British universities the members of the medical teaching staff migrated more frequently from one medical school to another. Such changes among the teachers of the advanced medical subjects are uncommon in this country, whereas in Germany and in America it is quite a usual custom to appoint a teacher from another university to a professorship or lectureship in one of these subjects.

Modern medical education may be conveniently considered as general and special. General medical education is the ordinary training which all students require to prepare them for a final or qualifying examination. Under the heading of special education may be included the more special or postgraduate training which is becoming more and more necessary for those who are preparing for one of the special branches of medical work or for one of the services. All those who wish to enter the medical profession must go through the five years' curriculum, and during this period the training is the same for all, as any specialisation in work

should be left until after graduation.

We must clearly recognise at the outset that the object we have in view in arranging a course of medical education is to train men and women to be as efficient medical practitioners as possible in the time at our disposal. It must always be borne in mind that our most important duty is to train men how to observe so that they may continue to be students and to go on learning all their days. There is rather a tendency to exalt the importance of teaching at the expense of training. Too much time and energy are expended on the mere imparting of knowledge in a form in which it may be readily absorbed and reproduced at an examination, while insufficient attention is given to training the student how to observe and act for himself. A medical man who can observe and make the best use of a moderate amount of knowledge often attains better results than one who has absorbed much knowledge and gained possibly many prizes but who has neglected to cultivate his powers of observation and action.

No. 4492.

The main object of the five years' course of education is to train and equip students as good all-round medical men, so that they may be able to take a resident appointment in a hospital, to take a special course of post-graduate work so as to obtain the special knowledge required for the navy, army, or public health service, or if needs be to proceed at once to engage in private practice. The general course of medical education, or as it is commonly called the five years' curriculum, is arranged on certain ines which are regulated by the General Medical Council. The details of the course and the amount of time allotted to each subject are left to the discretion of each medical school. The actual five years' curriculum is a minimum of 57 months from the time of registration to the time of passing the qualifying examination. This minimum period is too short for the average student to prepare for his final examination. The investigations of the General Medical Council have shown that the average time taken by some 1111 students to qualify for registration is only three weeks under seven years. Only 14 per cent. qualified in five years. It is evident, therefore, that either the present five years' curriculum is too short or that too much is crowded into it. In order to arrive at a more satisfactory state of affairs we must either lengthen or rearrange the curriculum. The new University of Bristol, recognising this at the outset, has fixed five and a half years as the minimum period, while the University of Wales has a curriculum of six years. The University of Belfast has, like the University of Durham, allotted only two years to preliminary subjects, leaving three years for hospital work and the final subjects. In our own University the curriculum has recently been rearranged, so that two years and one term are given to preliminary subjects, the remaining two years and two terms being left free for clinical work and final

The first year of medical work is devoted to the study of chemistry, physics, biology, and elementary human anatomy. The subjects are selected, not only because a knowledge of them is essential for the proper understanding of the later parts of the course, but also on account of the valuable training they afford for powers of observation, which require to be developed in every possible way. Chemistry and biochemistry, which has recently been added to our own curriculum, are becoming more and more important in daily medical work. Many students are imbued with the idea that once they have passed their first M.B. examination the only chemistry they really require is such as will enable them to prescribe correctly without mixing incompatible drugs and to carry out some simple tests for certain substances found in the excreta of patients in various diseases. This, however, is far from being the case, as the more physiological and pathological investigations teach us of the metabolism of the tissues in health and disease the more important a knowledge of chemistry becomes in the daily task of the diagnois and treatment of many maladies. We have, however, to arrange our courses of instruction in the preliminary subjects so as to leave sufficient time in the later part of the curriculum for the strictly professional subjects of medicine, surgery, and obstetrics. In order to do this recent changes have been made in this University which will prove to be an advance in the right direction. The classes in elementary biology, chemistry, and physics are now completed by the end of the first winter session, when the examination in them is held. Elementary anatomy is taken in the first summer session along with organic chemistry and bio-chemistry. The whole of the first examination should certainly be passed at the end of the first year. If no instruction in biology, chemistry, or physics has been received before entering the University this means a year of steady work. Many of our secondary and public schools now provide such good elementary teaching in these subjects that a boy on leaving school should already have acquired some useful knowledge of them.

The training for the navy has now become so special that a boy has to go to Osborne College as soon as he leaves a private school. Special classes for the army have for long been provided in public schools. If such early special train-

Thomson, in his recent presidential address to the British Association, protested against the early specialisation of school education for the sake of preparation for the scholarship examinations at the universities. There may be some danger of reducing the value of a general education when this is done to any large extent, but a boy can quite easily devote a sufficient amount of time to natural science and modern languages at school without unduly curtailing the scope of his general education. In order to encourage this, chemistry, physics, and biology should be made optional subjects in all entrance or registration examinations, or a student might have the option of passing the First M.B. examination on admission to the University. as at Cambridge. Speaking from personal experience, I should say the teaching in these subjects at some, at any rate, of our public and secondary schools, is excellent, and well adapted to the object in view. The education given at our public schools is often unjustly criticised, but I am a firm believer in its efficiency as a means of developing a boy's best qualities. If a student has made good use of his opportunities at school he should have no difficulty whatever in passing the examination in chemistry, physics, and biology by the end of his first year. In this University he is then free to devote himself entirely to anatomy and physiology during his second year and for the first half of his third winter session so as to pass his second examina-tion at the end of the Michaelmas term. The importance of a sound knowledge of anatomy and physiclogy cannot be over-estimated as a sure foundation for the more strictly professional subjects which follow. It is only by the careful study of anatomy and physiology that a detailed knowledge of the structure and functions of the body can be acquired which will enable a mental picture of any part of the body to be framed at will. I shall refer again to this power of mental vision in the diagnosis of disease, which is of such importance in medicine and for which a good practical knowledge of anatomy and physiology is the first essential. In arranging a syllabus for the preliminary subjects in any medical school it is most important that it should always be borne in mind that the ultimate object is the training of medical men. Many still believe, however, that these subjects should be taught as if for a degree in science. This, I am convinced, cannot be done, in the case of the majority, with satisfactory results in a five years' curriculum, without curtailing the time to be devoted to the more strictly professional training. When a man has the time to spare and the inclination he should certainly take a degree in science as well as in medicine, but for the majority of students the syllabus should only include what is likely to be of real use to them. Professor Starling has strongly urged that all unnecessary details in anatomy and physiology should be omitted so as to lighten as far as possible the load which the medical student is expected to carry.

In order to ensure the proper development of medical training it is important that each examination should be passed at the right time. No good purpose is served by attending lectures and classes in one group of subjects while the chief attention is directed to mastering another. Thus it is not advisable for a student who has failed to pass his first M.B. examination to attend lectures and classes intended to prepare him for the second examination before he has passed the first. This applies even more forcibly to later stages of the curriculum. A man can derive no benefit from attending lectures on medicine or surgery while all his energies are being directed to prepare himself for his second attempt to pass an examination in anatomy and physiology. If the percentage of students who fail to pass or to present themselves for examination at the right time is too high, it is usually an indication that the curriculum is overloaded rather than that the standard of the examination is too high.

When a student first commences work in a hospital he is apt to be bewildered by the mass of new facts with which he is suddenly brought into contact. It is therefore important that he should learn at the outting has been found advisable for these two professions, the time has certainly arrived when a larger amount of time has certainly arrived when a larger amount of time during the three or four years spent at a public or secondary school should be devoted to chemistry, physics and biology, as well as to French and German, by those who intend to enter the medical profession. Sir J. J.

practical knowledge of the diagnosis, course, and treatment of disease can be obtained, such as is required daily and hourly in actual practice. Many students are apt to overestimate the value of lectures and demonstrations as compared with individual work in the wards. In hospital training every opportunity must be given to students to examine and observe actual cases for themselves. Nothing is more conducive to this than the careful taking of notes in the wards and out-patient departments. In addition to taking full ward-notes for the hospital case-books every student should keep his own case-book and enter brief notes of all the cases he sees in the ward in which he works as clinical clerk, as well as of any other special cases he may have the opportunity of examining in the hospital. No cases leave a more lasting impression than those which are seen during this period of medical work, and they often serve as standard types with which to compare other cases seen later on in life. Many a man is able years afterwards to recall cases which he observed as a clinical clerk or house physician in the wards of his hospital with remarkable clearness, and so it is of the greatest importance that these early cases should be accurately observed and carefully noted. Such observations are greatly aided by reading the description of the disease in the text-book, as far as possible, the same day as the case has been seen, instead of postponing such reading until a later period.

In order to enable a student to make the best use of his time spent in hospital he first of all receives instruction in the methods of examining patients. This training in the various methods of making physical examinations is of the utmost importance to students, and is the foundation of good hospital work. I would urge all students to take the greatest pains to acquire this practical knowledge as far as is possible in the time allotted to it before beginning actual clerking or dressing in the wards, by regular attendance at the classes, and by the use of one of the excellent books on clinical methods. If a student fails to get a good grasp of this part of his work he will lose much of the benefit of his work as a clerk. In order to ensure full instruction in these clinical methods we should do well to adopt the mode employed in Johns Hopkins Hospital, where a number of instructors, usually young graduates living in the neighbour-hood, are appointed, who take only two or three students at a time for this work, so as to ensure the thorough training for every one of them which is so difficult to accomplish in dealing with larger classes. It is essential that the student should acquire the knowledge of how to use the laryngoscope and ophthalmoscope, as many lose valuable opportunities of seeing interesting conditions of the larynx and of the eye during their work in the wards because they failed to acquire the art of using these instruments at the outset. It is largely a question of practice, and there is no difficulty in accomplishing this by the aid of an obliging friend, to whom similar facilities may be granted in return.

One of the most recent developments in medicine is the great increase in the special means of investigating disease by the direct application of laboratory methods in clinical pathology. Many of these methods of examination are easily learned and are of great practical importance, as, for example, the routine examination of the blood, of various secretions and excretions by chemical, microscopical, and bacteriological methods. Every student at the Manchester Royal Infirmary now has a course of practical instruction in these methods, so that he may be able to employ them for himself in the course of his work in the wards. To facilitate the attendance of students at the infirmary the provision of a special residential hall in close proximity to the hospital is much to be desired, so that those who hold non-resident appointments may see as much hospital practice as possible. The hours at present allotted to work in the wards in some hospitals are insufficient. Ward work should be carried on for not less than two hours both morning and afternoon, so as to allow sufficient time for note-taking at a time of day when the medical staff are not visiting the hospital.

In no department of medical education has more remarkable progress been made than in the teaching of pathology. It seems superfluous now to emphasise the importance of a thorough knowledge of medical and surgical pathology and bacteriology to every student. This is necessary to enable him to understand not only the results but also the actual causes of many diseases. In comparatively recent times to the actual the superfluored was taught in our medical schools by one of the

physicians on the staff of the hospital. advantage in that it kept medicine and pathology closely in touch. Owing, however, to the rapid growth of pathology nearly all our universities now require the professor of pathology to devote his whole time to the subject, and in order that he may still be closely associated with clinical work it is essential that he should be ex-officio pathologist to the hospital and so a member of its staff, as is now the case in Manchester and other university medical schools. This arrangement is of the greatest advantage to both the university and the hospital concerned for the purposes of teaching and research. It would be a great advantage if we could have a ward set aside in each university hospital in which special cases could be observed and studied by the physicians and pathologist in association for the investigation of such questions as the changes in metabolism which occur in disease. Such a hospital is now attached to the Pasteur Institute in Paris for the investigation of infectious diseases. Special work in such a ward would be done by senior students or graduates preparing a thesis for the M.D. degree.

In actual practice the most important duty a medical man is called upon to perform, and one to which all else should lead, is naturally the treatment of disease. This at the present day includes a great deal more than the prescribing of suitable medicines. In this branch of his work the student has to learn how to deal with his patient as well as his friends and relations, so as to inspire them with confidence and hope. We hardly appreciate sufficiently how much this art, which in reality is but the expression of true sympathy and tact, may contribute to success. These are things which are not included in the curriculum. In the ordering of a patient's surroundings, mode of life, and diet, the exercise of common sense will often save the young practitioner from such errors of judgment as recommending expensive luxuries to patients who can barely afford the necessities of life.

With regard to the teaching of the uses of drugs we should do well to reduce the amount of materia medica which a student should learn to a minimum. As Professor W. E. Dixon has recently indicated, this is one of the subjects retained in the curriculum long after the need for it has ceased. On the other hand, more time should be devoted to pharmacology and therapeutics. All students should have a thorough knowledge of our chief and well-tried remedies. The list need not be a long one but he should be able to use them with confidence and even with boldness on suitable occasions. A first-hand acquaintance with many physical means of treatment, such as the use of heat, light, electricity, baths, exercises, &c., is important. The develop-ment of modern bacteriology has placed new methods of treatment, by means of vaccines and antitoxins, within our reach. The methods of preparing and using these remedies have now to be learned by students. A general knowledge of the influence of climate on disease and of the health resorts where special courses of treatment for certain chronic maladies can best be obtained will be useful, but special details can always be obtained from books when required.

Much of this knowledge will be acquired by degrees after qualification, but as it is I fear many men pass through their curriculum without taking the trouble to acquire as much knowledge of the methods of treatment as they should, and only realise when they are called upon to treat patients of their own how much they are expected to do and how limited their resources are.

In all English medical schools systematic lectures occupy an important part of a student's time. Three lectures a week are usually given in the major subjects. In the Scotch schools the number of lectures is even larger. Many opinions have been expressed about the utility of fixed courses of lectures. They are certainly perhaps not so essential now that text-books are so plentiful, but I maintain that as long as a student is not overburdened by having too many lectures to attend they serve a useful purpose. Much of the value undoubtedly depends upon the lecturer, and all who attended such lectures as those given by the late Sir Michael Foster on physiology or the late Mr. Marcus Beck on the principles of surgery realise how valuable such systematic courses may prove. I have had no personal experience of the recitations which in American medical schools have been substituted for regular lectures, but from what I can learn it appears that useful

as such classes may be they do not really take the place of our systematic lectures, though they may well be employed to supplement them. A systematic course of lectures should enable a student to take a good comprehensive view of the subject as seen by the lecturer, and the value of such lectures may be greatly enhanced by the use of specimens, diagrams, drawings, and lantern slides, to illustrate the subject under consideration, as in this way the visual as well as the auditory memory may be utilised in acquiring knowledge. In medical teaching it is so important to help students to acquire the power of mental visualisation, which is of so much value in helping them to understand the relationship between morbid processes and the symptoms of disease. The capacity to do this varies greatly in different individuals and appears to be connected with the power of imagination. Some seem to acquire it naturally without any conscious effort, as is shown by the possession of "number-forms" by some people and not by others. Number-forms, to which attention was drawn by Sir Douglas Galton, are imaginary lines along which many persons arrange numbers in a mental picture while counting. Many of them begin with a circle for the numbers up to 12, owing to these numbers having been originally learned from the face of a clock in childhood. The days of the week and the months of the year are also arranged in certain order along a line which can be visualised by many persons. By the study of anatomy and physiology the power is acquired of visualising all the various organs of the body, not only at rest but also at work, with as much ease in some cases as a mental picture can be formed of some familiar house or wellknown district in the country. If this has been accomplished a good foundation has been laid upon which to build a knowledge of disease.

In clinical work in the wards and in the out-patient room an endeavour should constantly be made to co-relate what is observed with the already acquired knowledge of anatomy, physiology, and pathology, not only by reading but by frequent attendance in the post-mortem room and reference to the specimens in the pathological museum. In this manner the power will in time be acquired of forming a mental picture of what appears to be the state of affairs in the patient. The picture thus constructed, in other words the diagnosis, will not always be correct, and even at times it will be rudely shattered by a necropsy, but having framed such a picture it will be instructive to trace the source of the error and to learn how to avoid it, if possible, in the future. To encourage this further, in some of the American schools a fatal case is gone over and reconstructed after death by the physician and the students from notes and observations taken during life, the conclusions being written up on a black-The specimens are then brought in and demonstrated by the pathologist, and if the diagnosis proves to be incorrect the cause of the error is fully considered on the spot. In cultivating this power of mental visualisation, however, it is most important to avoid the attempt to commit printed pages to memory. Some students do attempt to visualise pages of text-books of medicine or surgery, probably as a result of having learned to recite English or Latin at school. power is very highly developed in some people, and in one case I remember seeing it stated that the whole of "Paradise Lost" could be recited after reading it through once or twice, the reciter having retained as clear a mental picture of each page as if it were still before him. Such a method of learning medicine is, of course, quite useless.

No means of cultivating the power of rapid and accurate observation should be neglected, for many opportunities are afforded, not only by daily work, but also by holidays and recreations. Life in the country offers many opportunities of training the power of observation to the man who knows how to make use of them. Field sports and games are valuable in this respect and fortunate are those who are able to make use of them. Not only are the powers of observation constantly being called into play but a love of open-air life is acquired which will persist in after years, so that when the holiday season comes round the longing for a favourite pursuit will become so strong that at least one real holiday in the year will be taken, however brief it may be. Many a man loses the holiday habit simply because he has no absorbing pursuit to take him away from home and his ordinary surroundings, with consequent diminution in his health and efficiency. In no other profession is a man so

reasonable amount of holiday and recreation. duction of the motor-car has been a great advantage to medical men in various ways. Driving a motor has added new interests to the daily round of many a medical man, and not the least important of these is the training it affords in rapid observation and immediate action. A daily endeavour should be made to acquire a knowledge of the best English writers. Well-known members of our own profession have provided us with useful guidance in general reading and no student should fail to read and read again Professor W. Osler's "Equanimitas" and Sir Arthur Conan Doyle's "Through the Magic Door."

In this country degrees in medicine and surgery are usually conferred at once after passing the final examination. the University of Cambridge, however, a thesis has to be presented before the degree is conferred. In American universities the M.D. degree is awarded at once on graduation without further examination or test. In this country, this degree is only conferred after a thesis has been accepted or a special examination has been passed. The preparation of a thesis is a useful stimulus to post-graduate study, under which many men do useful work they might not otherwise have attempted. It would be a great gain if the work which is done for the M.D. thesis could be to some extent coördinated so that the work of several candidates might be upon differentaspects of the same problem. There are, of course, many practical difficulties, but it would be a decided advantage if each medical school selected certain subjects in medicine, pathology, or therapeutics, in which it could offer special facilities for work to graduates who were anxious to obtain the degree. One of the most hopeful signs of the times is the tendency to organise definite campaigns against certain diseases. In some cases the work has been done by a small but devoted band of workers, in others the work is being done on a larger scale by many individuals working with similar objects in view. The results already obtained by similar objects in view. this method within the space of a few years have been enormous. The active campaign against malaria and yellow fever has been most successful in diminishing the frequency of these preventable diseases. Much is now being done tolimit the advance of sleeping sickness in Central Africa by the practical application of knowledge gained by research. A great deal has already been achieved in diminishing the frequency of tuberculosis by the good work done by the National Association in making simple preventive measures more widely known and in encouraging the establishment of sanatoriums in many parts of the country.

The subject of cancer is attracting much attention, and the large amount of good work done in collecting information and investigating the disease by the Imperial Cancer Research Fund will surely in time lead us to a clear knowledge of the causation of the dire diseases included under this general term. Work has, however, been hampered for want of funds, and therefore it is most encouraging to hear that the munificent gift of £250,000 has recently been madefor a new cancer hospital in association with the special department at Middlesex Hospital. Manchester, too, is helping in the great investigation, and we only hope that the good work which is being done by Dr. C. Powell White may be continued and extended by the aid of further private generosity. In the case of the disease just mentioned, the machinery for investigation is ready and the responsibility now rests with the public to provide the necessary funds to maintain and extend it.

The time has, however, now come when similar organised attacks must be made on other groups of diseases, and at the present moment no disease calls so urgently for further investigation and prevention as pneumonia, using this term in its widest sense to include all conditions induced by infection with the pneumococcus. Tuberculosis and cancer naturally have attracted attention first, owing to the long periods of ill health and suffering they cause before the fatal termination is reached. Pneumonia causes more than 40,000 deaths in England and Wales each year. an enormous number to be caused by an infective disease which is, presumably to some extent at any rate, preventable. Although the disease is of short duration, how many tragic deaths are caused by it! The strong and vigorous man in the midst of a useful career is carried off after a few days' illness, or a young family is deprived of a mother's care at the time when it is most needed. constantly on duty and consequently more in need of a The University of Cambridge is making a special study

of another serious malady, rheumatoid arthritis, which cripples so many useful people early in life. The near proximity of the Devonshire Hospital at Buxton affords a magnificent field for the observation of this malady in this district. Rheumatic fever is another disease in which much might be done by combined investigation to diminish or possibly prevent the chronic ill-health and premature death which so often result from the irreparable damage received by the heart during an acute attack of the disease early in life. Such diseases as these offer a splendid opportunity for the foundation of research fellowships which might be tenable for one or two years to enable graduates to do research work which might be presented for the M.D. degree. I would not, of course, suggest that theses should only be accepted on the selected subject, as many would not be able to avail themselves of the special facilities. There are, however, many young graduates anxious to do work for a thesis but who are in want of a suitable subject and the facilities to investigate it. In the past only about one-seventh of our graduates have taken the M.D. degree. There are various reasons to account for this. The exigencies of general practice make it very difficult for a man to do the work for a thesis. To meet the difficulty the University lately instituted an examination for the degree as an alternative to the presentation of a thesis, and it remains to be seen if this fulfils its purpose. The difficulties of preparing a thesis are apt to be over-estimated. The mistake is often made in postponing it too long. All graduates who wish to proceed to the higher degree would do well to begin at once to select a subject and collect material for a A resident appointment in a hospital should be obtained soon after qualification, and there should be no real difficulty during residence as a house physician to make observations on cases and collect material to form the basis of a thesis. A few weeks or months spent in a laboratory to supplement this would much enhance the value of the work. This plan would be aided if some benefactor would endow such a scheme for coordinated research so as to enable willing workers to devote an adequate amount of time to it. In this University where we are so closely allied with a great hospital such a scheme should work well. A great deal of the most valuable research work in physiology, pathology, and medicine in this country is done by our younger physicians and surgeons during that golden period from 25 to 35 or 40 years of age, before so much time becomes absorbed by the claims of hospital appointments, teaching, and practice. It is therefore largely to the rising generation of consulting physicians and surgeons that we must look for advancements in medicine by means of research work done during this period, and to them the words of Tennyson may well apply-

"Men, my brothers, men the workers, ever reaping something new;
That which they have done but earnest of the work that they
shall do."

It is so easy to allow the first five or ten years after graduation to pass by in simply acquiring knowledge and enlarging clinical experience, but this is not enough for those who are entering consulting or special practice and aspire to be hospital physicians or surgeons and teachers, as an honest and sustained effort should be made to break new ground and make some useful addition to our common stock of knowledge. Such work not only brings its own reward in the feeling of satisfaction which accompanies any useful achievement, but also in reputation and practice in the years to come. In the early years of practice much can be accomplished by giving certain hours each day to work of this kind or by devoting one whole day or two half-days each week to some special work. Still better it is when by means of a research scholarship a man can devote half or even the whole of his time to research work for one or two years. At the present time such research scholarships or fellowships in medicine are too few in number. Much good original work has been done by the holders of these scholarships and it is a great gain for practical medicine to have among its ranks many who have thus added greatly to our knowledge by research work carried out soon after graduation. It is the special function of a university to encourage this work, for the work of all universities is not only to train men and impart knowledge but also to make new knowledge, and it is desirable that a larger proportion of the resources of each university should be devoted to this purpose.

We are gradually approaching a time when, after the ordinary course has been completed and the qualifying examination has been passed, many students will devote six months or a year to more special work. This is already done in the case of those who are going to enter the services or who intend to become medical officers of health. A similar special course of instruction followed by an examination will in all probability shortly be inaugurated in psychological medicine for those who wish to become medical officers in our asylums. Those who are going to devote themselves to one of the special branches of medicine or surgery will naturally devote as long a period as possible to work at the subject of their choice. It would be a great advantage if some more practical instruction in the daily work of general practice could be given under the supervision of those who have had wide experience of this work, as so many recently qualified men who are obliged to start practice at once find themselves very incompletely equipped for their work. The system of pupilage with a general practitioner during the fifth year was intended to meet this difficulty, but few men appear to avail themselves of it; indeed, considering the amount of work which has to be accomplished in the five years it is much better to postpone the acquiring of the special knowledge of general practice until after qualification. The majority of students are preparing for this arduous and exacting work, in which a wide general knowledge of internal, external, and obstetric medicine is essential, and above all the power to observe accurately and to act promptly in emergencies.

The conditions of general practice are unfortunately often extremely trying, and owing to altered conditions of work and the developments of preventive medicine the field for general practice has in some directions become more restricted than it used to be. While the field for general practice has been curtailed in some respects, we must recognise that there are now more official posts to be obtained by medical men than formerly. The public health service is always increasing, and we may look forward to a time when the administrative work of preventive medicine will be entirely in the hands of specially trained medical officers of health. Every county will then be divided into districts, each of which will have a whole-time medical officer of health with one chief officer for the county to coordinate the work of the whole area. Every public health authority will have a working arrangement with the bacteriological department of the nearest university, where all the bacteriological examinations will be carried out in the manner so successfully originated and developed by Professor Delépine in Manchester and now also in operation in many other medical centres; so that there are ever increasing opportunities for work in these different branches of preventive medicine. In this branch of work there are now complete courses of post-graduate training and a special diploma which is awarded after an examination. Closely connected with this work is the medical inspection of school children, work which will prove to be of inestimable value to the community at large. number of medical men are required for this work and thus occupation will be provided for many who prefer definite hours of work at a fixed, though small, remuneration to the uncertainties of private practice.

The services offer a career to many which, owing to recent changes in methods of training and work, is yearly becoming more attractive. Owing to the recent developments which have taken place under the stimulating direction of Sir Alfred Keogh, the work of the Royal Army Medical Corps will attract many of the best men from our medical schools. The opportunities which are now given to suitable men to carry out original research in military hygiene are admirable and have already borne fruit. As one example I need only remind you of the discovery of the Micrococcus melitensis as the cause of Malta fever by Sir David Bruce and the tracing of this source of infection to goats' milk. The prompt application of preventive measures founded on the knowledge thus acquired has stamped out the disease in the military population of Malta. The amount of sickness which has thus been prevented is incalculable. In appealing to the public to endow research more liberally it is of interest to point out, in addition to these advantages. that in this case the actual saving in special food for the sick and in the expense of sending invalids home alone amounts to no less than £15,000 a year. Another question which is being investigated by the Royal Army Medical Corps is the occurrence of typhoid carriers and the best method of dealing with them. The special conditions of the army afford opportunities for investigating this difficult question which are almost unattainable in civil practice. The special difficulties of dealing with these cases have been admirably illustrated by Owen Seaman in Punch, who describes how Mary, the Irish cook—

"Herself immune and full of beans,
A state her ruddy cheek confirms,
They say she runs behind the scenes,
A tolling factory of germs;
Wherever, rosy and robust,
She was engaged to boil the victuals,
The family would bite the dust,
Falling about her path like skittles.

Our Mary being shut away For two whole years to get her clean, Is just as germy as the day On which she went in quarantine."

It is our object so to train men that they are capable of making observations for themselves in whatever department of medicine their future career may lie. Those who go into general practice are apt to consider that they have no opportunities for making observations and adding to our general stock of knowledge. This is not so, and good work can be done in general practice in this respect. In fact, there are many important phases of disease which can be better observed in general practice than in hospital wards. The splendid work done by Dr. James Mackenzie at Burnley in applying new methods of observation to the investigation of cardiac disease, and by Mr. A. Maude of Westerham by the accurate and continued observation of Graves's disease shows how much can be done by those engaged in private practice. Once the habit of recording observations is acquired it is not difficult to continue it, and even those who start practice as soon as they have graduated may make useful records of some disease prevalent in the district and so in time gather together useful material for a thesis. Such records may be kept by devoting a short time each day to the work and are in themselves a means of continuing medical education and afford a most valuable method of training and improving the powers of observation.

All those who can would do well from time to time in after life to visit a medical school and obtain post-graduate instruction so as to bring their knowledge up-to-date. On the continent facilities for these holiday courses have long been provided and have proved most attractive. In this country and in Scotland post-graduate courses are now also well arranged to suit the requirements of men who can only spare a short period in the year for such work. Many would do well to imitate the good example of Cullen and William Hunter who were in partnership and made an agreement that each would alternately spend the winter in study while the other carried on the practice. By some such arrangement with a partner or friend a fortnight's post-graduate work every second or third year ought not to be beyond the reach of the majority of medical men.

In conclusion, I should like to congratulate all of you who are entering the medical profession upon the wisdom of your choice, and to wish you all success as students now and as practitioners in the future. To quote the words of Sir Benjamin Brodie: "I know of no profession that is worthy of being pursued which does not require as much exertion, as much labour, as many sacrifices as that in which you are engaged, and I also know of none in which he who has the necessary qualifications is more sure of being rewarded for his labours." Remember that even when you are finally established in practice you will still be students ever striving to acquire greater skill and more knowledge so that you may be in the best position possible to assist all those who come to you for help. Cultivate friendly relationships with your fellow practitioners and avoid all petty jealousies. We may well admire the conduct of Dr. Richard Mead, who would only consent to attend Sir Robert Walpole on the condition that Dr. Friend was released from prison, to whom he then presented a bag containing 5000 guineas, the amount of the fees he had received for him during his imprisonment. In the words of Professor Marx: "The best regulation for the medical profession consists in dignified humanity: this will prescribe, in the simplest manner, its relation to the State, to science, to the public, and to the University. Pure morals, able qualifications, thorough cultivation, are the safest guides.

Abstracts

OF

INTRODUCTORY ADDRESSES, ETC.,

DELIVERED AT THE

MEDICAL SCHOOLS

AT THE

Opening of the Session 1909-10.

ST. GEORGE'S HOSPITAL.

INTRODUCTORY ADDRESS BY H. D. ROLLESTON, M.D. CANTAB., F.R.C.P. LOND., SENIOR PHYSICIAN
TO THE HOSPITAL.

DR. ROLLESTON took for his subject "St. George's Hospital and the Progress of Physic." He said: The objects of the introductory address may be numerous, but the most important motif should be one of welcome to the future, present, and past students. The future students, or those who are here for the first time, may be congratulated on joining a school with famous traditions. It is well on such an occasion as this to recall the achievements of our predecessors so as to keep their memory green, and thereby to stimulate esprit de corps and proper pride in our school. In attempting to record the influence of St. George's men on the advance of our professional knowledge I shall confine myself to medicine as apart from surgery, and as "medicine" on these occasions is commonly used for the whole healing art I must employ the old-fashioned and perhaps pedantic word "physic" to indicate the scope of my remarks.

One of the most distinguished of our physicians was Matthew Baillie, who held office from 1787 to 1800. Trained under the eyes of his uncle, John Hunter, it is not sur-prising that he was early distinguished by publishing, in prising that he was early distinguished by publishing, in 1793, the first book in the English language devoted solely to morbid anatomy. "The Morbid Anatomy of some of the most Important Parts of the Human Body" went through five English editions up to 1818, and was translated into French, German, and Italian. It differed from the monumental work of Bonetus, "Sepulcretum seu Anatomia Practica" (1700), and from Morgagni's famous "De Sedibus et Causis Morborum" (1761), in being restricted to morbid anatomy and not dealing with the records of clinical cases. anatomy, and not dealing with the records of clinical cases, or with the relations of morbid lesions and symptoms. of small size compared with modern works on the same subject, and consists almost entirely of personal observations. Baillie first recognised cirrhosis of the liver, though not under that name which was invented by Laennec in 1819. as a disease distinct from "scirrhous" tumours; he spoke of it as "common tubercle of the liver." He also first pointed out that "polypi of the heart" were really blood-clots, and drew a distinction between cysts and hydatids of the kidney. This work was subsequently supplemented by "An Atlas of Modern Anatomy" (1799–1802), illustrated from his private collection of morbid specimens which he presented to the Royal College of Physicians in 1819, four years before his death. His influence on the study of morbid anatomy was most fittingly recognised by the Pathological Society of London, a medallion of his face being embossed on the cover of the Society's Transactions surrounded by the motto "Nec silet mors." The lamp that he lighted was kept burning at his own hospital by his successors, Brodie, Hope, who published a beautifully illustrated work on "Morbid Anatomy" (1834); by Cæsar Hawkins, Sir Prescott Hewett, G. D. Pollock, Dr. W. H. Dickinson, and Dr. J. F. Payne, who may be specially mentioned as Presidents of the Pathological Society, and by John Ogle and Holmes. Baillie appears to have been a pioneer in the routine physical examination of patients. "Baillie's pill" (pilula digitalis co.), containing digitalis leaves, blue pill and squill, is much the same as the diuretic pill at Guy's. In 1808 Baillie was the second President of the Medical and Chirurgical Society, which, in 1834, became the Royal Medical and Chirurgical Society, and in 1907 was merged into the Royal Society of Medicine. Of the 51 presidents of this the premier medical society in London, St. George's has had its full share, viz., nine—four physicians: Baillie (1808-9), Ohambers (1845-6), Barclay (1881), and Dickinson (1896-7), and five surgeons:

Sir B. Brodie (1839-40), Casar Hawkins (1855-6), Pollock (1866-7), Holmes (1890-1), and Haward (1906-7).

Thomas Young, the most comprehensive genius and the greatest man of science who ever became a member of our profession, was physician to this hospital from 1811 to 1829. He was an example of the old adage that "a prophet is not without honour save in his own country," for it was not until it had been recognised and approved abroad that his great conception of the undulatory theory of light attracted attention in England. He wrote an encyclopædic "Introduction to Medical Literature," and formulated a "System of Nosology (1813), or a classification of diseases arranged in classes, orders, genera, and species on the lines initiated by Linnæus in the natural sciences. Nosological classification was then a burning problem in medical science and there were numerous rival systems, of which, to mention only those of British origin, Cullen's, Erasmus Darwin's, and MacBride's preceded Young's, whilst Mason Good's came out later. Dr. Young's Nosology is very different in arrangement from those of his predecessors, among whom he specially criticises Cullen, is full of bibliographical research, and contains numerous strange names of Greek origin for familiar diseases. In 1815 he brought out "A Practical and Historical Treatise on Consumptive Diseases" deduced from original observations and collected from authors of all ages. The practical part is interesting from the scattered references to the somewhat heroic methods of treatment employed in Dr. Young's own case, for, like many other eminent men of our profession, such as Sir James Paget, Sir Andrew Clark, Sir Michael Foster, he appears to have had pulmonary tuberculosis, but to have recovered. His death in 1829, which was preceded by hæmoptysis and weakness, was ascribed to "ossification of the aorta." For pulmonary tuberculosis in earlier life he had tartar emetic in small doses for hectic fever, had a blister which was kept open for a year, was bled twice, and was in the habit of riding daily.

The services rendered to physiology and so to pure medicine by John Hunter are too wide-reaching to be detailed. Like Hunter, Brodie's physiological and pathological work entitled him to be included among "The Masters of Medicine" series brought out by Fisher Unwin, his life being written by the late Mr. Timothy Holmes. Brodie was the first surgeon, the only other being Lord Lister, to be President of the Royal Society. In this connexion it is interesting to note that the only physicians who have occupied the presidential chair of the Royal Society are Sir Hans Sloane (1727-1740), Sir John Pringle (1772-8), and Wollaston (1820) who, however, threw up this profession in disgust when he was rejected in 1800 as a candidate for the office of physician to St. George's

Of Edward Jenner's discovery of vaccination and its influence on medicine it is impossible even now to realise the full significance. For over a century Jenner's name has been immortal for the prevention of small-pox, and what the future will bring forth in the application by Sir A. E. Wright of vaccine treatment to the prevention and cure of disease it is

impossible to estimate.

In addition to such epoch-making advances there are many points—now so amalgamated into text-book medicine that their sponsors are almost forgotten-concerning which St. George's Hospital may justly feel some proprietary pride. The materials for forming an estimate of these advances are, however, somewhat scattered, and many observations of value must have escaped me. It has been truly said that there is no profession in which a man may be so distinguished in his lifetime and leave behind so slight a record of his life as in medicine. This applies to some of our past physicians, such as Teissier, Broxolme, Sir R. Jebb, Gisborne, R. Warren, and Chambers, who held Court appointments, but never had the time or inclination to record their experience and observations.1

The cardio-vascular system has been a favourite study with our professional ancestors. Hope (1832) and Fuller (1863) wrote systematic works on the subject, and some of the early experimental work on the causation of the sounds of the heart was done in the dissecting-room of the Kinnerton-street School of Medicine, attached to St. George's Hospital, by Hope and his rival, C. J. B. Williams, in 1834 and 1835. These two were candidates for the post of physician in 1839, Hope having in 1835 been elected to the post of assistant physician, then officially established for the first time. The unsuccessful candidate—Williams—was almost at once appointed professor of medicine at University College, and became well known as an authority on diseases of the lungs and as the first president of the Pathological Society. His son, Dr. Theodore Williams, educated at our school, has shown his appreciation of scientific research by generous benefactions to Oxford and to the Royal College of Physicians. Hope described the early diastolic murmur of mitral stenosis, now regarded as caused by pulmonary regurgitation due to backward pressure and dilatation of the pulmonary artery—the pulmonary diastolic murmur of high blood-pressure—but although he looked for a murmur, produced by the auricular systole, before the contraction of the ventricle, he never recognised the presystolic murmur, which was first described in 1843 by Fauvel. The presystolic murmur was criticised by Dr. A. W. Barclay (1872) and by Dr. W. H. Dickinson (1887), both of whom, while fully acknowledging its distinctive characters and diagnostic significance, contended that it was systolic and not presystolic. One of the first descriptions of a ballclot in the left auricle in mitral stenosis was given by Dr. John Ogle in 1863. Pulmonary apoplexies, first really described by Laennec in 1819, were shown to be specially associated with mitral disease by Dr. J. A. Wilson in 1830. This observation, now universally accepted, was very briefly reported, and the original manuscript was only published in 1896 in the St. George's Hospital Gazette by his grandson, Dr. Lee Dickinson. Dr. Robert Lee, the first obstetric physician to the hospital, was well known for his minute dissections of the ganglia and nerves of the heart.² The diagnosis during life of mitral regurgitation by physical signs was really first made possible by Hope's work on the heart. Edward Jenner discovered that angina pectoris depends on disease of the coronary arteries. As is well known, John Hunter suffered from angina pectoris for the extremely long period of 20 years—from 1773 to his death from that disease in this hospital in 1793. In 1776 Jenner saw Hunter, diagnosed his disease, and wrote to the elder Heberden, who was one of Hunter's medical advisers and had recently given a clinical account of the malady, mentioning two cases in which necropsies showed coronary disease. Jenner, however, refrained from making his discovery known out of consideration for the feelings of his friend Hunter. The view now generally held as to the causation of angina pectoris— namely, coronary obstruction—has been contested since 1894 by Sir Clifford Allbutt, who maintains that it is a painful affection of the first part of the aorta, coronary obstruction being a complication and not a necessary factor. Angina pectoris, he argues, is not itself the cause of death, which is due to some additional lesion, such as myocardial or valvular disease. Light was thrown on the pathology of angina pectoris by Sir Benjamin Brodie's observations on intermittent claudication or limp, resulting in muscles supplied by arteries narrowed by disease.

To the work of active members of the staff it would be unbecoming to refer, and as he is so often with us I have hesitated to refer to Dr. Ewart, but in justice I cannot entirely refrain, and must recall his valuable observations on the signs, early and late, of pericarditis with effusion.3 In 1866 Sir Clifford Allbutt was instrumental in introducing into this country the operative treatment of pericardial effusion; J. Ogle and Holmes were among the first to describe aneurysms due to embolism. syphilitic disease of the cerebral arteries was first described by Sir Clifford Allbutt, then of Leeds, in our Hospital Reports (1868, iii. 55) more than 40 years ago. The estimation of arterial blood pressure by instrumental means, which has now come to be an ordinary method of clinical investigation, owes its position in no small degree to the advocacy of the present Regius Professor of Physic at

Cambridge.

Respiratory system. - When the Royal Humane Society was first started John Hunter was appealed to for advice, and in 1776, on the basis of some old but unpublished experiments, he suggested artificial respiration by means of bellows and the employment of oxygen, then recently discovered by Priestley. In 1821, however, as the result of Sir Benjamin Brodie's influence, the society abandoned the use of the

^{&#}x27;1 For the lives of the early physicians to the hospital reference may be made to papers by Mr. G. C. Peachey in the Hospital Gazette (1902, x. 94; 1908, xiv. 25).

² Philosophical Transactions, 1849, 1851. ³ W. Ewart: Brit. Med. Jour., 1896, i. 717.

bellows. St. George's had a good deal to do with methods for the resuscitation of the apparently drowned; Dr. Bowles assisted Dr. Marshall Hall in the elaboration of the method which bears his name, and wrote on this subject, and on which bears his hand, and wrote on this subject, and dis-stertor and its mechanism (1860), pointing out that the dis-tressing stertor and cyanosis of a patient with cerebral hæmorrhage can be rapidly removed by turning him from the dorsal to the lateral position. Dr. Champneys, when assistant obstetric physician, investigated the problem of artificial respiration in the newly born, and pointed out the mechanism by which pneumothorax occurs after tracheotomy. The anatomy of the bronchi and the localisation of cavities in chronic pulmonary tuberculosis were elucidated by Dr. Ewart in 1882. Among the numerous workers on pulmonary tuberculosis none in London has been more consistent than Dr. Theodore Williams, whose name is specially connected with climatic and sanatorium treatment and also with aerotherapeutics. The first specimen of plastic bronchitis shown at the Pathological Society was that described by Dr. Fuller in 1854.

Digestive system. — The epoch-marking discovery that cholera is conveyed by water was made in 1854 by Dr. John Snow, who gave his services to the hospital as anæsthetist. Almost the first case of a pulsion diverticulum at the junction of the pharynx and cesophagus ever published was reported by Dr. John Ogle in the Pathological Transactions for 1866. For many years—in fact, until the early "nineties"—this condition remained a pathological curiosity, but, like many other quondam rarities, it has become a matter of common know-Iedge—probably a hundred cases are on record—and is now recognised as being readily curable by surgical measures. Dr. J. Ogle also contributed valuable papers on diseases of the abdomen and liver, which are so full of careful observations that anyone who comes across some rare and possibly undescribed morbid condition would do well to consult them before publishing his discovery. Lee Dickinson, both alone and with Mr. Warrington Haward and Dr. Penrose, made a careful investigation into the clinical aspects of gaseous subphreric abscess. Disease of the vermiform appendix is such a hackneyed subject now that it is rather surprising to find that as late as 1886, while arguing that so-called "typhlitis" and "perityphlitis" are both due to disease of the appendix, Fagge brings as proof of this a case recorded by Dr. Theodore Williams. Ulceration of the intestines in chronic renal disease was described by Dr. W. H. Dickinson s as albuminuric ulceration, apparently quite independently of Traube's earlier account of the same condition as uræmic ulceration. Dr. Theodore Williams first described pigmentation of the colon from the long-continued ingestion of mercury.

Diseases of the kidneys.—Among the older physicians to the hospital Dr. Donald Monro (1758–1786) wrote on "Dropsy, and its Various Species." Dr. Bence Jones was a recognised authority on chemistry in application to medicine, especially as regards diseases of the kidneys and disorders of digestion, and thus led the way to modern work on metabolism. He described one of the first urinary calculi composed of cystine; and his name is perpetuated in connexion with Bence Jones's protein, or the albumose found in the urine of patients suffering from multiple myeloma of bones. In 1848 he described "A New Substance occurring in the Urine of a Patient with Mollities Ossium"; it seems certain, however, that the disease was not mollities ossium, but the condition of multiple myeloma, described by Kahler, and sometimes called Kahler's disease. Of Dr. W. H. Dickinson's numerous contributions to medicine, the most exhaustive is his great work on "Diseases of the Kidneys"; closely associated with this are his researches on the pathological and clinical aspects of cedema, on granular kidney and the accompanying cardio-vascular changes, on diabetes, and on lardaceous disease. The first full account of uremic skin eruptions in this country was published by Dr. Le Cronier Lancaster 7 in 1892.

Nervous system. - Dr. Dickinson 8 pointed out that atrophic

changes occur in the central nervous system after amputation of limbs, and together with Dr. John Ogle argued against Kirkes's once popular view that chorea was due to multiple cerebral emboli. Sir Prescott Hewett and Dr. J. Ogle described the "arachnoid cysts" with which they endowed our museum. Dr. W. Ogle, the translator of Aristotle, "On the Parts of Animals," who resigned the post of assistant physician in 1872 to direct the vital statistics at Somerset House, his relative, Dr. John Ogle, and Dr. Wadham 10 discussed the explanation of aphasia. In his first paper Dr. W. Ogle 11 confirms Broca's then recent localisation of the speech centre by a number of cases; and in his second contribution he deals with aphasia due to snake-bite. Dr. John Ogle's clinical lecture on aphasia contains interesting historical references to the cases of Dr. Samuel Johnson and Dean Swift. 12 The first case published in this country of "locomotor ataxia with hydrarthrosis" was put on record in the fourth volume of our Hospital Reports by Sir Clifford Allbutt in 1869, the year after Charcot described this condition, which is now usually called after him. He also was one of the pioneers in the introduction of the ophthalmoscope into general medicine as a means of diagnosis (1871), and wrote especially on the ophthalmoscopic appearances in the insane (1868). The normal temperature of the body and the influence on it of physiological conditions, such as exercise, were investigated by Dr. William Ogle and by Sir Clifford Allbutt, and to the latter we are indebted for the present form of the clinical thermometer, as is recorded in the following extract from the catalogue of the Museum of Scientific Apparatus, South Kensington, 1876: "Dr. Atkin used thermometers 10 in. long, and the instrument was hardly met with beyond the wards of a few hospitals. In 1867 Dr. Clifford Allbutt requested Messrs. Harvey and Reynolds to make for him instruments with a chamber anterior to the bulb, reducing the length of the tube from 10 in. to 6 in., then to 4 in. and to 3 in." The temperature in certain nervous diseases, especially tetanus, was investigated by Dr. John Ogle 13 in 1872.

Duotless glands, &c.—In 1846 Fuller demonstrated the blood-picture of spleno-medullary leukæmia, which had been described only the year before by Hughes Bennett in Edinburgh and by Virchow; and in 1880 Dr. Cavafy. 14 then lecturer on physiology, found that only a small percentage (12) of the leucocytes showed amœboid movement. Since 1905 it has become clear that in cases of primary tumours arising in the cortex of the suprarenal bodies (hypernephromas) there may be precocious development, especially of the sexual organs and skin. But 40 years before this Dr. J. Ogle 15 recorded a well-marked example of this association in a child, aged three years, the water-colour drawing of whose body and the tumour being in our Museum. One of the first cases illustrating the now accepted law that primary carcinoma of the thyroid is especially prone to produce secondary growths in bone, was published by Mr. Warrington Haward ¹⁶ in 1882. Dr. H. Watney investigated the histology of the thymus gland. Dr. Cheadle, who, like some other St. George's men, migrated to St. Mary's Hospital, did much to broaden our conception of the rheumatic process, especially in children, and was one of the first to recognise the condition of infantile scurvy. The condition of the viscera in rickets was elucidated by Dr. W. H. Dickinson; and Dr. D. Drewitt interested himself in the rare form of late rickets. Sir Clifford Allbutt provided Sir James Paget with one of the cases on which he based his well-known description of osteitis deformans, one of the conditions spoken of as Paget's disease.

Hypodermic medication.—It is now over fifty years since the method of hypodermic injection of drugs was introduced by Dr. Alexander Wood of Edinburgh. In 1853 he first practised hypodermic injection of morphine for the relief of neuralgia, and an account of this great advance in treatment was published in 1855 as a "New Method of Treating Neuralgia by Subcutaneous Injection." At first the injections were given in the painful part only. It was,

indeed, in the wards of St. George's Hospital that neuralgia was first treated by suboutaneous injection at a distance from the seat of the pain, and that the hypodermic method was first employed for other than neuralgic affections. This advance was initiated by Mr. Charles Hunter, at that time house surgeon to the hospital, who in 1866 contributed to the first volume of our hospital reports a paper entitled, "Remarks on the Modus Operandi of Hypodermic Injections." Very shortly after this—namely, in 1869—Sir Clifford Allbutt "published the remarkably good results of what was then quite an unknown form of treatment—namely, the injection of morphine in bad cases of heart disease. Snow, who introduced the scientific use of ether anæsthesia into England, worked at St. George's (1847–1858) as ansesthetist.

Treatment of rheumatic fever. - It is fairly safe to say that next to morphine and anæsthetics the drugs most effective in the relief of pain are salicylic compounds. Probably few of the present generation know that in July, 1889, the physician who was largely instrumental in introducing this treatment of rheumatic fever into England, the late Dr. T. J. Maclagan, was an unsuccessful candidate for the post of assistant physician to this hospital. Maclagan, 18 then of Dundee, first published an account of the action of salicin in rheumatism in 1876. It is true that Stricker of Vienna had just begun to employ salicylic acid in the treatment of rheumatic fever, and that Sir W. Broadbent had already obtained good results at St. Mary's Hospital on these lines. The influence of salicylates on rheumatism was in 1876 tested in the hospital by Dr. Cavafy and Dr. Whipham, who thereby helped to confirm the utility of the treatment. Before the introduction of the treatment by salicylates the course of rheumatic fever was very different from that now seen. In 1860 H. W. Fuller 19 wrote: "If the contradictory nature of the treatment recommended for the cure of acute rheumatism be taken as test of its obstinacy and intractability, it certainly is the most tedious and untractable of diseases." Historical interest attaches to the 13 methods of treatment tabulated by Dr. Fuller-namely, bleeding, purging, opium, vapour and hot air baths, mercury, tartar emetic, cinchona, colchicum, guaiacum, nitrate of potash, blist ring, lemon juice, alkalis and their salts. Probably the most successful of these methods of treatment was the alkaline treatment as expanded by Dr. Fuller.

In 1894 or 1895 we were, by the foresight of our then Dean, Sir Isambard Owen, the first school to recognise tropical medicine as deserving of a special lectureship and were fortunate in securing the services of Sir (then Dr.) Patrick Manson as lecturer. The pioneer, if not the founder, of the scientific study of tropical diseases in India was an old St. George's man, H. Vandyke Carter.

St. George's men have also influenced medicine as Regins Professors at Oxford and Cambridge. At Oxford Dr. J. A. Ogle was Professor from 1851 to 1857, and was then succeeded by Sir Henry Acland, who resigned in 1894, after having done so much to render pessible the present flourishing condition of that school. At Cambridge Sir Clifford Allbutt has held the chair since 1892, and as Professor Osler is attached to our teaching staff as Thomas Young lecturer we could not be more highly represented at the older universities. The Armstrong College of Science at Newcastle-on-Tyne enriched itself at our expense by taking Sir Isambard Owen, whom, though he should still be our senior physician, we most cordially congratulate on his recent appointment as Vice-Chancellor of the University of Bristol.

Lastly, St. George's men have influenced the progress of medicine in a manner often overlooked, but none the less important, by the editorial control of medical journals. Dr. Roderick Macleod, one of our physicians, was first editor of the Medical and Physical Journal, which Dr. Sprigge, who now edits The Lancet, describes in his "Life and Times of Thomas Wakley" as "a decent monthly magazine of some 90 pages with no particular reason for its existence." At that time Wakley was sigorously attacking abuses in the medical world in the pages of The Lancet, and the two journals came into opposition, the strained relations eventually landing the rival editors in the law courts. In 1827 Macleod left the Medical and Physical Journal to direct the Medical

Gazette, which was started by some leading hospital surgeons, including Brodie and Abernethy, to counteract the "evil influences" of The Lancer, but it must be admitted that it was not very successful in the fight against Wakley and his energetic methods. The British and Foreign Medico-Chirurgical Review, which was conducted on much the same lines as the Edinburgh Quarterly, and probably marked the highest level of medical journalism in this country, was for a time edited by Dr. John Ogle.

LONDON SOHOOL OF MEDICINE FOR WOMEN.

INAUGURAL ADDRESS BY MRS. HENRY FAWCETT, I.L.D. Mrs. Fawcett said she had chosen the subject of pioneering because she felt that they were, one and all, and she spoke for herself as well as to the students, too apt to step in and enjoy what had been won for them by the labours of their predecessors as if it had been bestowed, like manna from Heaven, as the bounteous gift of Providence without a thought of the years of courage and self-sacrifice which had been necessary to attain it. The enthusiasm and the genius of the pioneer had been sung by modern poets. She referred particularly to Walt Whitman and Mr. Rudyard Kipling; the latter especially had shown in his poem "The Explorer how keenly he had entered into the spirit of the pioneer. The vision, the sacrifice, the compelling necessity, came to one man in a million; he moved forward and showed the way, then the mass followed and enjoyed the fruits of his labours and hardly gave a thought to him who had put these advantages within their reach. She recognised that this was in a sense quite wholesome and natural. Just as a healthy person never thinks about his health, so those who enjoy what others have won seldom think how those benefits were attained. Still, there was a certain ungraciousness and ingratitude in accepting all that had been won by the labour of others without any sort of acknowledgment. There was only one really valid excuse for this attitude, and that excuse was ignorance. But, after all, complete as the excuse was, it was one of which it was scarcely possible to be proud. Mrs. Fawcett proceeded to make a brief allusion to Mrs. Garrett Anderson's pioneer work in opening the medical pro-fession to women in England, ably seconded as she was by Dr. Sophia Jex-Blake, Dr. Edith Pechey-Phipson, and others, but she dwelt at greater length on the pioneer work done in the same direction some 15 years earlier by another Englishwoman in the United States, Dr. Elizabeth Blackwell, who was still happily to be numbered among our contemporaries. She dwelt on Dr. Blackwell's innumerable difficulties and indomitable spirit in overcoming them; on her essential womanliness (it was characteristic of her that she never lost her English nationality though she was 40 years resident in the United States, and in the same way she never lost the least shade of her womanliness); and on her deep interest in the moral and religious aspect of her professional work. The students of the present day could scarcely have a more interesting and charming work in their hands than Dr. Blackwell's auto-biography called "Pioneer Work in Opening the Medical Profession to Women," published by K. Barry of Hastings. In conclusion, Mrs. Fawcett said that the students she then saw before her would go on their several paths out into the world, and although they themselves would know that they were not pioneers, that the real pioneering had been done for them by their predecessors, yet they might very probably find themselves in positions where the qualities of a pioneer would not be misplaced, and in this case she hoped that something of the pioneer spirit might be vouchsafed to them. The pioneer cleared away obstructions and difficulties, made the road plain and safe for those who followed. If they really wished to recognise with gratitude the work which had been done for them by the great pioneers of the last century, she could wish nothing better for them than that they also should deserve, though they might not receive, the gratitude of those who followed them in the noble profession to which they were preparing to devote their

THE ASSOCIATION OF PUBLIC VACCINATORS OF ENGLAND AND WALES.—This association will hold its annual dinner at the Adelphi Hotel, Liverpool, on Oct. 29th, at 6.30 P.M. The secretary is Mr. Charles Greenwood, 1, Mitre Court-buildings, Temple, E.C.

also light loss, but when it is of normal length and brightness this is not the case. It is evident that we are dealing with two distinct conditions. All who have had practical acquaintance with the subject of colour-blindness are aware that all dichromics (so-called red-green blinds) are not equally colour blind. One dichromic will put a very full red and green together, but another will object to this, but will put together as a match a red and green occupying a relatively nearer position in the spectrum. The dichromic with the smallest neutral band in the centre of the spectrum, separating the two colours red and violet, has the best colour perception. This, it will be seen, is a prediction from the theory, and is inexplicable on any other. A dichromic with the smallest neutral band is very difficult to detect with any of the usual tests, and will generally pass them with ease. The reason of this is that a dichromic of this kind sees about six distinct differences in the spectrum; he sees green as a lighter and greyer colour than red, and distinguishes between them just as a normal-sighted person distinguishes between bluish-greens and blues. This is how the colour-blind match wools. The dichromic are, therefore, those who see two true colours and grey. They regard red, orange, yellow, and half of the green as one colour; the other half of the green, blue, and violet as the other. The presence of a neutral band causes the colours corresponding to this portion of the spectrum to be seen as grey. Therefore the larger the neutral band the more colours will be classed as grey. If the rays which fall within one colour of the dichromic be mixed with those which fall within the other. grev will be the result. Therefore violet and red, instead of making a purple to the dichromic, make a grey, which is indistinguishable to them from the grey made by blue and green.

The next stage of evolution of the colour sense is when the colour-perceiving centre is sufficiently developed to distinguish three main colours in the spectrum. The third colour, green, appears in the centre of the spectrum—that is, at the third point of the greatest difference of refrangibility of the rays. In accordance with the prediction of the theory, I found a considerable number of persons who saw the spectrum in this way, about 1 5 per cent. of men. Sir William Ramsay and Sir J. J. Thomson belong to this class which I have designated "trichromic." The trichromic see three main colours in the spectrum-red, green, and violet. They usually describe the spectrum as consisting of red, redgreen, green, green-violet, and violet. They do not see yellow and blue as distinct colours, and are therefore in continual difficulty over them. There are very few of the tests in general use which can detect them, especially if names be not used. They will usually pass a matching test with ease. An examination with the spectrum shows that their colour perception is less than the normal in every part, though the curve has the same general shape. The three trichromics described in my recent paper on "Observations on Hue Perception" each saw ten consecutive monochromatic patches in the spectrum instead of the 18 or 19 seen by those who see six colours in the spectrum. It is easy to show that the trichromic are dangerously colour-blind. They will mark out with the spectral apparatus a patch containing greenish-yellow, yellow, and orange-yellow, and declare that it is absolutely monochromatic. When tested with coloured lights they find great difficulty with yellow and blue.
Yellow is continually called red or green.

There are several other degrees of colour perception, and it may be well to say a word or two about them, though I class all above the trichromic with the normal-sighted for practical purposes, as they are not dangerously colour-blind and can always distinguish signal lights correctly. In the next stage of evolution four colours are seen in the spectrum, and the fourth colour appears at the fourth point of greatest difference of refrangibility—namely, at the orange-yellow of the hexachromic or sixunit people; these persons I have designated "tetrachromic" because they see four distinct colours in the spectrum—that is, red, yellow, green, and violet. They do not see blue as a definite colour, and are continually classing blues with greens: they usually prefer to call blue, purplish-green. In the next stage in evolution there appeared those who see five colours in the spectrum—red, yellow, green, blue, and violet, blue being now recognised as a definite colour; these are the

pentachromic group. These people pass all the tests in general use with ease; they, however, have a definitely diminished colour perception compared with the normal or those who see six colours in the spectrum. They mark out in the spectrum only 15 monochromatic patches instead of 18. They cannot see orange as a definite colour; for instance, they can never tell whether a strontium light, which is red, or a calcium light, which is orange, is being shown them. In the next stage of evolution orange is recognised as a definite colour, and thus we get the hexachromic or normal group, and, as we should theoretically expect, the yellow of the pentachromic is now split up into two colours-orange and The last stage of evolution which we appear to have reached are those who see seven colours in the spectrum, and the additional one is called indigo. These constitute the heptachromic group, and this seventh colour appears at the exact point which it should appear according to my theory—namely, between the blue and the violet. Persons belonging to this class have a marvellous colour perception and memory for colours. They will indicate a certain shade of colour in the spectrum, and then next day will be able to put the pointer at precisely the same point-a feat which is quite impossible to the ordinary normal-sighted person. They see a greater number of monochromatic patches in the spectrum than the hexachromic, but the curve has the same form. The marking out of the heptachromic does not appear correct to those who see six colours; for instance, the blue appears to invade the green and the indigo does not appear a definite colour at all. If, however, we bisect the blue of the seven-colour man and then bisect his indigo, on joining the centres we get the blue of the six-colour man, showing most definitely that the blue has been split up into two fresh colours.

It will be noticed that there is room for much further evolution, and we could go on splitting up the spectrum indefinitely if only we had the power to distinguish these finer differences, but, as a matter of fact, I have never met with a man who could see more than 29 monochromatic patches in the spectrum, and there are really millions, though by monochromatic patches I do not mean 29 separate colours. Time will not permit me to give an explanation in this paper of all the facts of vision and colour vision, according to this theory. I have dealt with the chief facts in my book on "Colour Blindness and Colour Perception," in the International Scientific Series, and various papers. I am not aware of any fact which does not support the theory. Hendon, N.W.

A NOTE ON THE PATHOLOGY OF LEAD POISONING.

BY KENNETH W. GOADBY, M.R.C.S. Eng., L.R.C.P. LOND., D.P.H. CANTAB.,

PATHOLOGIST AND LECTURER ON BACTERIOLOGY, NATIONAL DENTAL HOSPITAL;

AND

F. W. GOODBODY, M.D. DUB.,
ASSISTANT PROFESSOR OF PATHOLOGICAL CHEMISTRY, UNIVERSITY
COLLEGE, LONDON.

The symptoms of lead poisoning have been known for many years, and the literature relating to the subject is enormously large. Great as is the number of works, no initial stage of unanimity has been reached concerning the pathology. There are three conceivable channels by which lead may enter the system—namely: (a) through the gastro-intestinal canal; (b) through the respiratory system; and (c) through the skin. For many years the first of these channels was considered to be the one of primary importance, possibly owing to the prominence of colic as a symptom; but more recent investigation, particularly the statistical ones of His Majesty's Chief Inspector of Factories and the Chief Medical Inspector of Factories, have determined that the incidence of industrial lead poisoning varies directly as the dust produced in the particular lead industries. In 1905 one of us (K.W.G.¹) instituted a series of experiments to test the possibility of producing lead poisoning in animals by causing them to inhale lead dust in the form of fine white lead dust obtained

⁹ Transactions of the Ophthalmological Society, 1907.

¹ Goadby, Kenneth W., Journal of Hygiene, vol. ix., April, 1909.

from the exhaust ventilation air duct flues in a white lead works, such dust, for instance, as the workmen are exposed to during the packing of dry white lead. These experiments pointed very definitely to the lung rather than the stomach as the source of poisoning, animals fed with a gramme of lead carbonate per diem surviving those which inhaled

0.3 gramme every third day.

These preliminary experiments have been followed up by a further and extended series of experiments in which other compounds than white lead have been used for the investigations, and we have demonstrated that during the inhalation of finely divided lead compounds lead in the form of dust enters the lung, and becomes absorbed by the tissues of the lung, the lead being demonstrable in the alveoli of the lung, and at times in the protoplasm beyond, and that by lung absorption all the symptoms of lead-poisoning take place. The amount of lead dust present in the air in factories in which poisoning takes place amongst the workers is very much smaller than the quantity of lead present in the air of our inhalation cage. Thus Duckering ² estimates the amount of lead present in the total respired air of a man working in a tinning factory as about 0.014 gramme per diem. The amount of lead present in our cage air varied from 0.0001 gramme to 0.001 gramme per litre; and allowing for the respiration of the cat at about 50 cubic centimetres per respiration, and a respiration-rate of about 25 per minute, the cat would inhale 0.03 gramme of lead during the 30 minutes it was exposed in the cage, this being every other day, and occasionally with three-day intervals; three months were required to produce unmistakable clinical symptoms. The quantity of lead found in the air of tinning factories is much larger than is the amount present in the air in the potteries, but it is not much in excess of the quantity present in dusty processes in white lead works. Our experimental conditions were certainly more severe than those of industrial processes. Still, from an experimental point of view it is of the greatest importance to induce the poisoning as rapidly as possible, providing always that the clinical symptoms of the animals are comparable to those of man under natural conditions. This we found to be the case. The animals suffered from emaciation which was progressive, paralysis, and in many instances died with symptoms suggestive of involvement of the brain. These symptoms are analogous and, we believe, homologous with the saturnine cachexia seen in lead workers, the wrist-drop and other forms of paralysis, and finally acute encephalopathy and lead mania.

Compounds of lead other than white lead were also used, and in every case symptoms similar to those observed in man have been produced. The other compounds of lead used were lead acetate, litharge, lead dust from de-silverising works, and lead bisilicate of a form used in the potteries. The animals used for experiment have been mainly cats (35), though one dog was used. These animals are especially susceptible to lead poisoning, and it is common knowledge that when kept as domestic pets in lead works they soon develop lead poisoning. In three instances we have ad-ministered alcohol in addition to lead, and find that alcohol increases the susceptibility and diminishes the latent period of lead poisoning. Careful post-mortem examinations have been made of the animals that died. The tissues have been examined histologically with a view to determining the primary action of lead on the animal tissues and to establish the specific pathological lesions produced. We desire here to express our warm appreciation and grateful thanks to Dr. H. R. Clark, who has undertaken the histological examination of the nervous tissues and has also given us much valuable help and advice.

The material that comes into the hands of the pathologist in cases of industrial lead-poisoning is generally derived from chronic poisoning, rarely of acute poisoning, and it is particularly in these cases that a diagnosis of "death from lead poisoning" is an exceedingly difficult one to make. The literature, as has already been stated, is very extensive, and at the same time remarkably contradictory. Kobert, in summing up the general effect of lead on the animal body, states that "lead attacks especially the striped and unstriped muscles, the epithelium of the excretory glands, the neuroglia of the central nervous system, and it is especially a protoplasmic poison." The principal clinical manifestations of lead poisoning are lead colic, lead paralysis, and

perhaps lead encephalopathy. It is in the pathology of these symptoms that the greatest variation is to be found in the records of different workers.

One series of observers consider that the action of lead is directly upon the central nervous system, producing on the one hand colic and on the other paralysis of the motor nerves, as in the extensor paralysis of wrist drop (Quensel, Rudolf Meyer, Gesenius, &c.). On the other hand, Küssmal and Paul Maier, Mossé and Galvini describe sclerosis of the solar plexus, cœliac ganglia, and also—particularly Eichorz 10 -consider that the damage is one mainly located in the spinal cord. Another series of observers, among whom may be named Riegels, 11 who examined 200 cases of colic, and Jaccoud and Weber, 12 consider that such symptoms as colic, amaurosis, and amblyopia are referable to vaso-motor spasm of the blood-vessels, particularly in colic to the inferior mesenteric arteries, actual stasis producing the amaurosis. Galvini 13 describes in a man of 54 who was subject to chronic saturninism and who died in a condition of extreme cachexia, perihepatitis, perisplenitis, wasting of the stomach, liver, and spleen, and inflammation of the solar plexus. Paul Maier 14 found sclerosis of the connective tissues of the coeliac plexus. Further, a later series of observers, amongst whom are Gravitz, 15 Litten, 16 Hamel, 17 and Keil, 18 describe a degeneration of the red blood corpuscles as an early symptom of lead poisoning. This consists of an altera-tion of the protoplasm of the blood discs with basophile staining. Some observers think that the peripheral nerves and the motor nerves undergo degeneration, as did Prevost and Binet. 19 Nissl 20 describes characteristic degeneration of the cortical cells of the brain. And, finally, Glibert, 21 who fed a number of rabbits on lead carbonate in the form of pills, found congestion and stasis of the liver, fibroid changes and emphysema in the lungs, and kidney degeneration of a fibroid nature, and occasional microscopical hæmorrhage. Oliver 22 notes kidney degeneration of a parenchymatous nature in rabbits poisoned with white lead, and Weber 23 and Virchow 24 describe degenerative nephritis. There is thus a considerable difference of opinion as to the exact action of lead, but distinct consensus of opinion that its pathological effects are widespread.

We think it will be possible to show by the histology of our animals that any one of the symptoms and histological findings described is consonant with the primary effects of lead intoxication-namely, microscopical hæmorrhages, affecting practically all the tissues of the body, as well as the nervous system, central and peripheral. A detailed account of our experiments is out of place here, and we have therefore summarised our results. The lead compounds were administered by inhalation, hypodermic injection. and

feeding.

SYMPTOMS PRODUCED.

1. Loss of weight.—In all cases during the early stages of the experiments, in which the animals became ultimately poisoned, the weight at first increased, but subsequently fell progressively until the animal had lost one-third, sometimes two-thirds, of its body weight before it died. The control animals kept in the laboratory did not show this variation, but maintained a steady level of weight. The animals fed on white lead have so far exhibited no signs of lead poisoning, and there is at the present time in the laboratory an animal

which has been fed on white lead for eight months, at first with 0·1 gramme, then with 0·5 gramme, and finally 1·0 gramme of lead per diem. This animal even now exhibits no signs of poisoning. Three other animals fed on white lead, &c., for shorter periods show no signs of poisoning.

2. Paralysis.—The paralysis in our animals has been generally confined to the hind limbs. Those animals which have been inoculated with either acetate, carbonate, or bisilicate of lead died exhibiting signs of paralysis. The knee-jerks are at first increased and then become sluggish; considerable wasting of the muscles takes place; the animals tire upon the least exertion, a run of 24 yards completely exhausting an animal that is passing under the influence of lead. The animals also adopt voluntarily a oharacteristic attitude; when taken out of their cages the animals at first stand with their hind legs well extended, the position of the knee-joint being normal. In a few seconds the quadriceps extensor slowly yields and the animals finally crouch or sit down. At the post-mortem examination the muscle is wasted and flabby. When the animal rolls over on its side and attempts to rise afterwards there is considerable difficulty in extending the knee-joint, the animal getting up with a jerk of its other muscles. In advanced cases the animals are only able to jump three or four inches from the ground.

3. Mental condition.—The animals remained perfectly friendly until the paralysis became well established, and it was often difficult to listen to their hearts with a stethoscope on account of their persistent purring. Finally, a distinct mental change was noticed, the animals became torpid, then irritable, highly nervous, and developed well-marked intention tremor, all pointing to cerebral irritation. In three instances fits occurred immediately before death; in one case the fit was of an epileptiform nature, commencing with twitchings and ending in clonic spasm.

4. Eyes.—In two instances amaurosis was present. The reaction to accommodation and light is invariably sluggish or entirely lost; the retinal vessels were tortuous and hæmorrhage was seen in one instance. The loss of reaction

to light and accommodation was noticed by one of us (K. W. G.)²⁵ in the first series of animals experimented

upon.

5. Post-mortem appearances. - All the animals that died were submitted to an exhaustive necropsy. The post-mortem appearances were practically identical in all the animals: there was an entire loss of all subcutaneous and mesenteric fat, and the omentum was practically non-existent. Occasionally the diploë of the skull was deeply congested, more especially in the inoculated animals. The liver and intestines were injected, the liver especially being engorged with blood. The lungs as a rule were normal, but rather full of blood, and in the animals subjected to inhalation the bronchial glands were found enlarged and often full of blood. There was practically no fat around the kidneys, but the capsule of the kidneys stripped easily. In one or two instances shrinkage of the cortex was noticed, but the most prominent symptom was the marked injection of the vessels on the surface of the kidney. The kidney on section was engorged with blood. No extravasation of blood was seen in the peritoneal cavity, except in one instance where a hæmorrhage had occurred near the suprarenals and in the region of the kidney. Small punctiform hæmorrhages were at times found in the stomach, in the duodenum, and the rest of the intestine; they were more marked in the lower end of the intestine and particularly around the ileo-cæcal valve.

Further, in animals which had not received any lead by the mouth at all, and in which the poisoning was produced by the subcutaneous injection of a lead compound, there was very distinct blue-black staining of the upper half of the cæcum and extending up into the vermiform appendix. The spleen was normal. The muscles were normal but flabby; where paralysis had existed the corresponding muscle was found diminished in size. The surface of the brain appeared normal, but the vessels were somewhat larger than in a normal animal. The vessels of the spinal cord were also somewhat increased in size, but there were no obvious hæmorrhages, nor were any macroscopical hæmorrhages found on making sections of the brain.

6. Histological examination. - Portions of the heart, lungs,

liver, spleen, intestines, stomach, and kidneys were preserved in formalin, cut in paraffin, and stained by Heidenheim's hæmatoxylin and eosin, and by van Geissen's method. Portions of the anterior crural nerve supplying the paralysed quadriceps extensors were examined in celloidin and also sections of the spinal cord and the cortex of the brain. This portion of the histology was undertaken by Dr. R. H. Clark. In all the tissues examined a distinct engorgement and increase in size of the blood-vessels were found; here and there the smaller vessels, particularly the capillaries, were over-distended, and in addition numbers of minute microscopical hæmorrhages were everywhere apparent in the brain, cord, liver, kidney and lung, &c.

In the kidneys the same microscopical hæmorrhages were seen with some slight changes in the epithelium of the tubules and a small amount of parenchymatous inflammation, no doubt due to the hæmorrhages which had taken place. The kidney, on the whole, seemed to suffer less than the lungs or liver. And in this connexion it is worth noting that clinically no obvious signs of blood are noticeable in the urine of persons suffering from lead poisoning. Thickening of the arteries in the various organs was not well defined; the veins rather than the arteries appear to be the source of the hæmorrhages. In the anterior crural nerves supplying the paralysed quadriceps extensor minute hæmorrhages were found between the nerve bundles, but not generally invading the nerve bundles, nor was any degeneration found either in the nerves supplying the muscle or in the sections of the cord examined; in places it was seen that the hæmorrhage was producing pressure. Hæmorrhage was also found under the pia arachnoid, which was somewhat thickened. The whole histological picture was one of microscopic

The whole histological picture was one of microscopic hæmorrhage occurring in the various organs and tissues, and it is evident that the minute hæmorrhages are the precursors of the fibroid and scierotic changes that pathologists have seen in the tissues derived from cases of lead poisoning. Moreover, it is important to note in this connexion that not a few of the symptoms in lead poisoning have been ascribed to stasis and vaso-motor spasm or vaso-constrictor spasm of the various blood-vessels. In poisoning by nickel carbonyl Armit 26 has shown that the poisoning is due to the nickel and not to the CO, that the nickel is absorbed through the lung, and that injections of other nickel salts produce the same pathological changes as inhalation of nickel carbonyl. In animals poisoned by nickel minute hæmorrhages occur in

all the tissues, especially the brain.

Further, and of great importance, Mott describes in a recent paper 27 in the Archives of Neurology and Psychiatry the histology of a case of fatal lead encephalitis, in which he found minute hæmorrhages due to the breaking down of the cortical vessels of the brain, degenerative hyaline thickening of the walls of the small vessels, together with a hyper-trophy of the branching glia cells. The case described by trophy of the branching glia cells. Mott was a coach-painter, who developed lead poisoning at his work. The clinical symptoms were progressive loss of power, epileptiform seizures, followed by a mental condition of restlessness and irritability, paralysis, tremor, fibrillary twitchings, impairment of vision, tortuosity of retinal vessels, all exactly conforming to the symptoms noted in our experimental animals. Histologically the heart, spleen, liver, and lung of Mott's case showed fibroid thickening with a condition of angio-sclerosis in which arteries and veins were involved; the head of the cæcum was darkly stained. The kidneys showed interstitial fibrosis and hyaline degeneration, while the vascular coils in the capsules were frequently replaced by a hyaline purple-staining mass. Microscopical hæmorrhage was found in the spinal cord; the vessels showed thickening and hyaline de-The staining of the lower part of the intestine, particularly in the region of the ileo-cæcal valve, is a point of considerable importance, as much of our work points to the excretion of lead by way of the fæces, and in our animals which were poisoned by inoculation, lead was undoubtedly present in the large intestine, the staining of the lower part of the intestine being similar to that noted by Newton Pitt.

We conclude, therefore, from our experiments that the essential and primary action of lead intoxication is the

Armit, H. W.: Journal of Hygiene, vol. viii.; Proceedings of the Royal Seciety, vol. lxxvii., p. 420.
 Mott, F. W.: Archives of Neurology and Psychiatry, vol. iv., p. 117.

preduction of minute and microscopical hæmorrhages in various portions of the body, including the nervous system. That the clinical symptoms of lead palsy, and its good prognosis when treated early, are explainable by the presence of minute hæmorrhages in the peripheral nerves. The presence of these minute homorrhages in the nervous system also gives an explanation of the varied pathological findings of many previous workers.

STUDY OF SPINAL ANÆSTHESIA IN CHILDREN AND INFANTS.

FROM A SERIES OF 200 CASES.

BY H. TYRRELL GRAY, M.A., M.C. CANTAB., F.R.C.S. Eng.,

RESIDENT MEDICAL SUPERINTENDENT, HOSPITAL FOR SIGK CHILDREN, GREAT ORMOND-STREET, LONDON.

(Continued from p. 917.)

II.—A STUDY OF THE SECOND SERIES OF 100 CASES.

IT is apparent from a critical study of the first series of cases that in a considerable proportion of these there are certain disadvantages which, though not serious in themselves, may detract from the utility of this method in the surgery of children. For instance, the occurrence of any of the symptoms recorded in the previous contribution in a case where serious collapse was present might add considerably to the critical condition of such patient and make it doubtful whether there is any advantage to be gained over general anæsthesia.

In the first series there was a boy about nine years of age suffering from streptococcal general peritonitis. The advisability of interference was considered, and, as general anæsthesia was out of the question on account of the extremely collapsed condition of the patient, it was decided to attempt operation under spinal anæsthesia. A small injection (3 centigrammes stovaine) was administered and the peritoneal cavity thoroughly cleansed, the whole operation lasting about 45 minutes; during this time there were no symptoms of shock and the gravity of the child's condition was in no way accentuated. There was no vomiting during the manipulation of the intestines, nor did any signs of toxemia, pallor, sweating, &c., supervene. The child died shortly after his return to the ward, or rather over an hour from the time of the injection. An interesting feature was the striking absence of shook during the manipulations within the abdomen, and, further, three points in the case present themselves for consideration as accounting for the death :-

1. The disease. - The peritonitis was so advanced and general, and the patient so clearly toxic, that I think it possible death might have occurred within an hour or two if no operation had been attempted. It was clear, in any case, that the administration of general anæsthesia would not have permitted more than incision and drainage of the abdominal cavity, if as much.

2. The injection.—Against the view that the injection of stovaine accelerated death is the important fact that in all cases in this series where any symptoms were present, these supervened at the latest within 20 minutes from the administration of the anæsthetic. It is extremely unlikely, therefore, that the progress of the disease was accelerated by any of the toxemic symptoms referred to, for these should have made themselves evident earlier, and the boy should have manifested serious symptoms during the progress of the operation.

3. On no occasion in the first series did I succeed in obtaining anæsthesia of the abdomen of more than one hour's duration. I think it probable, therefore, that the shock of the manipulation made itself felt as the anæsthesia of the abdomen was passing off, and that it was this factor which added to the gravity of the collapse due to the disease and

contributed to the fatal result.

Whichever of these views be accepted, however, it is clearly desirable to abolish or minimise, if possible, symptoms which, though they do not materially influence the course of routine operations, may add considerably to the existing collapse in "desperate" cases, where the use of spinal ansesthesia is so strongly indicated. The prevention of the eccurrence of these symptoms is only possible if we have an

accurate knowledge of their causation, and this I now propose to consider.

Mr. W. Peck, chemist to the Hospital for Sick Children, has during the last ten months been kind enough to spend a great deal of time and trouble in making all the chemical and physical observations I have asked of him-and his results, controlled and repeated, have been of great value. It has been estimated by Dr. J. Graham Forbes that the normal amount of cerebro-spinal fluid in the body is about two ounces. He states that the solids average about 1 per cent. and include 0.8 to 0.9 salts and 0.1 to 0.2 proteid and extractives. It is the salts which are of the greatest importance in the subject under consideration, and these are approximately as follows: - Sodium chloride, 0.7; potassium chloride, 0.03; alkaline and earthy phosphates, 0.013 to 0.02; and sulphates and carbonates, traces. These figures are, of course, subject to considerable variation under different physiological conditions.

In a series of normal children, from whom I obtained cerebro-spinal fluid on the operating table, the specific gravity was found to vary from 1.0054 to 1.0071, the fluid of older children tending to be of a higher density than that of infants and younger children. In extreme collapse, however, as would be anticipated, there is a considerable increase in the specific gravity of the cerebrospinal fluid. Thus in two infants with advanced intussusception the cerebro-spinal fluid was 1.0080 and 1.0076 specific gravity; in another case the specific gravity rose to 1.0083. Since this variation is largely due to the crystalloid substances, the depression of the freezing point or the osmotic pressure of the cerebro-spinal fluid alters accordingly, and I hope to show that this is of some importance in connexion with the safety and utility of spinal anæsthesia. In the explanation of the unpleasant symptoms referred to authors have differed widely. Mr. A. E. Barker,2 for instance, attributes fainting and collapse to the fact that the paralysis of the abdominal muscles so far relieves intra-abdominal pressure that the large veins become engorged with venous blood, and so a cerebral anæmia is produced. From the experience in my own cases I have been unable to satisfy myself that this factor plays more than a very small part, if any, in the production of these symptoms and for the following reasons:-

1. These complications have not infrequently occurred in cases of low anæsthesia when there has been no paralysis of the abdominal muscles.

2. The abdominal muscles have frequently been completely paralysed without any untoward symptoms resulting.

3. In every laparotomy I have performed under spinal ansesthesia I have examined carefully for signs of venous engorgement but without success.

This last reason has led me also to disbelieve the further statement that in these cases symptoms are due to paralysis of the splanchnic nerves and the resulting arterial hypersemia of the viscera, for I have always noted, and frequently demonstrated to others, the definite anæmia and pallor of the intestines during spinal anæsthesia.

4. If there were any marked tendency to engorgement of the mesenteric veins this factor would only be of importance in the erect position and should be counteracted (to a very great degree, at any rate) by the raised pelvis position employed by Mr. Barker or by the Trendelenburg position, adopted by many surgeons, especially on the continent. I have not found the former a controlling factor.

5. The onset of the symptoms takes place from 10 to 20 minutes after the injection of stovaine when the paralysis of the abdominal muscles has been present for some time (i.e., about 15 minutes). Further, the onset of pallor has been noted as being delayed as long as 25 to 30 minutes on occasion.

6. If Mr. Barker's explanation were the correct one, it would be expected that the vomiting would follow the pallor and the cerebral ansemia, but the reverse is the usual

sequence.

I have been led to believe, therefore, that the etiology of these complications is to be sought for in another direction.

Now, in administering a spinal anæsthetic, fluid of a much higher specific gravity and a rapid diffusibility has hitherto been introduced into the spinal theca. Mr. Peck has

¹ Graham Forbes: Estratto dai Lavori e Riviste di Chimica e Microscopia Clinica, vol. i., Fasc. ii. and iii., October-November, 1908.

9 Brit. Med. Jour., March 23rd, 1907.

estimated for me the osmotic pressures of the various fluids used as indicated by their depression of the freezing point. Thus :-

TABLE I.

Cerebro-spinal fluid (from an average of 4 cases)		D.F.P.		0.61°C
1. 1 % sodium chloride		D.F.P.		0.65°
2. 5 % glucose		D.F.P.		0.540
3. Normal saline (used in the second series)		D.F.P.		0.600
4. Normal saline and dextrin (6.5 %)		D.F.P.		0.65°
5. Glucose-stovaine solution (5 %) (5 %)	•••	D.F.P.	•••	1·20°
6. Dextrin-stovaine, normal saline				
(4 %) (2½ %)		(for 2 estin	mai	ions).
(No. 6 is Fluid 1a, referred to in	Tal	ole II.)		

It is thus seen that, though theoretically dextrin should not yield any depression of the freezing point, yet in actual practice this does take place to a very slight extent owing to small traces of sugar present in the solution, especially after prolonged heating. I shall refer again to this table of osmotic pressures.

Now the fate of a fluid of high diffusibility and specific gravity can best be ascertained by considering the physiology of the cerebro-spinal fluid. For information on this subject I will refer to Dr. Leonard Hill's book on the "Cerebral Circulation." Dr. Hill in this work gives his own observations and those of other authorities, and as their results seem to me to have an important bearing on the subject under consideration I shall draw largely from the statements in this book. Thus Adamkiewicz states: "That every tendency of the cerebro-spinal fluid to take up a higher tension than normal is stopped by the passing of fluid into the blood, and this resorption goes on till the tension is equal to the blood pressure." Though it is important to know this, it is of still greater moment to know at what part of the cranio-vertebral cavity absorption of fluids takes place to the largest extent and with the greatest rapidity. "Falkenheim and Naunyn passed a catheter up the cauda equina into the subarachnoid space and allowed normal saline to run in from a pressure bottle. At a pressure of 15 mm. Hg absorption was apparent but very slow. At a pressure of 59 mm. Hg it reached 1 c.c. a minute. When a ligature was drawn round the dura at the level of the second or third cervical vertebra so as to cut off the spinal from the cranial cavity, the rate of absorption was lessened from 6 c.c. in 10 minutes to .6 c.c., the pressure of the injection being 40 mm. Hg. According then to the result of this experiment, the oranium is the chief seat of absorption."

Dr. Hill further has found that saline injected at any pressure above the cerebral venous pressure disappears from the cranio-vertebral cavity, and that the higher the pressure the more rapid its disappearance. Saline coloured with methylene blue could be traced passing straight into the venous sinuses, and in so short a time as 10 to 20 minutes the blue colour could be found secreted in the stomach and in the bladder. Dr. Hill concludes that this absorption takes place by way of the veins and not the lymphatics, and that the human dura permits of easy filtration of fluids (namely, at 40 mm. Hg). Therefore at moderate pressures fluids in the cranio vertebral cavity can evidently pass quite easily direct through the dura into the venous sinuses. Experiments are recorded in support of these statements.

It has been shown that under abnormal pressures both secretion and absorption of fluid from the cranio-vertebral cavity become filtration. "Under normal pressures, however, the secretion and absorption of cerebro-spinal fluid does no doubt follow osmotio laws," for Professor Halliburton and others are quoted by Dr. Hill as having found that "cerebro-spinal fluid, when originally drawn off from the subarachnoid space, has a peculiar chemical composition, but on being drawn off again and again, after refilling of the space, it equals more nearly the composition of serum."

That there is another pathway than the Pacchionian granulations at the cavernous and longitudinal sinuses, by which fluid in the cranio-vertebral cavity can be absorbed, is proved by the experiment of Reiner and Schnitzler, who found that potassium ferrocyanide injected into the cranium of rabbits was found very rapidly in the jugular vein. Dr. Hill states that the most favourable condition for increasing the outflow of cerebro-spinal fluid is a high arterial tension (increasing transudation) coupled with a high venous tension (preventing

To return to a consideration of my first series of cases. When stovaine-glucose solution (or any other solution of a high diffusibility and specific gravity) is injected into the subarachnoid space it spreads over the nerve roots up and down by several methods.

1. Diffusion.—This is by far the most important method, for whereas the cerebro-spinal fluid has a very high freezingpoint the fluid injected has a considerably lower one.

2. Gravity.—This factor is also of great importance, as has been most clearly demonstrated by Mr. Barker.

3. Force of injection.—This factor, together with the disturbance of the cerebro-spinal fluid resulting, will also help to distribute the solution.

By a combination of these three factors the fluid must travel up the spinal subarachnoid space towards the cranial cavity, until all the fluid in the cranio-vertebral cavity has the same osmotic pressure. This travelling of the fluid towards the cranium is greatly accelerated by debility or collapse, when the arterial and venous tensions are below normal (vide supra).

I have not mentioned a fourth factor by means of which it is held that fluids may travel towards the cranium-namely, by a shifting of the entire column of fluid in the craniovertebral cavity with the change of position of the body (Bier and Donitz). I have not included the view because it seems so difficult to understand how a whole column of fluid which completely fills a more or less closed cavity can suddenly change its situation with a change of posture. injected fluid must therefore soon reach the cranium. (Mr. Barker, as has been previously stated, has made a great advance on continental methods in endeavouring to prevent this by the action of gravity, and he has no doubt succeeded to a great extent, but not completely, for he has not eliminated the most important factor—namely, diffusion.)

Now, once the injected fluid has reached the cranial cavity, though the solution of the anæsthetic agent is too dilute to give rise to any dangerous local paralysis (provided the dose be reasonable), we have several factors to consider which I think can almost be proved to be the main cause of the unpleasant complications referred to. In the first place, the freezing-point of the cerebro-spinal fluid is lowered; its osmotic pressure consequently is higher. Therefore, by osmosis fluid will pass from the venous sinuses into the cranio-vertebral cavity, while stovaine and glucose will pass from this cavity into the venous sinuses. If this occurs to any extent-i.e., when solutions of a very high specific gravity are used—there should be a diminution of venous tension in the cranium, and secondarily also of arterial pressure, so that the conditions most favourable to absorption are established (vide supra). Two factors in the production of the sequelæ under discussion thus assert themselves:—

1. The mere fact of fluid passing from the venous sinuses into the cranio-vertebral cavity will suddenly, if only temporarily, diminish the intracranial blood pressure and might be sufficient to cause syncope. In healthy subjects whose arteries are elastic the circulation can easily re-establish the normal conditions, but in patients who are the subjects of arterio-sclerosis it is conceivable that so rapid a diminution of the intracranial pressure might not be so quickly compensated and a more serious condition result.

2. The main effect, however, of this sudden diminution of intracranial tension is to accelerate still further by filtration the absorption of the toxic agent into the circulation, for we have seen that, at the same time, the tension of the cerebrospinal fluid is increased by the passage of fluid into the cranio-vertebral cavity.

It follows that the injection of the fluid, intended to produce spinal anæsthesia only, really establishes, to a more or less marked extent, three factors which all tend to promote the absorption of the toxic agent. It is interesting to read Dr. A. E. Russell's views as to the etiology of epilepsy and petit mal, set forth in the Goulstonian lectures of this year. Dr. Russell considers the exciting agent of an attack of petit

absorption). It is the laws of absorption of fluid from the cranio-vertebral cavity under normal pressures which concern us most in studying the question of spinal anæsthesia. if the quantity of fluid injected be not very great the pressure will not be very appreciably altered.

mal or of the major syndrome to be primarily circulatory in origin, and he adduces evidence to show that a cerebral anæmia starts the fit. It is possible, therefore, that the patients who exhibit a tendency to syncope under spinal anæsthesia belong to this class of subject and are the victims of constitutional conditions similar to those predisposing to epilepsy and petit mal. For the syncopal attacks seen under spinal anæsthesia are in many respects similar to petit mal and even amount to epileptiform attacks, and may perhaps be excited by the rapid diminution of intracranial pressure above alluded to. This view might account to some extent for the apparent idiosyncrasy in such cases.

If these suppositions are correct the administration of spinal anæsthesia by means of diffusible solutions is definitely contra-indicated in subjects of arterio-sclerosis, and in this connexion it is interesting to note that most of the deaths under spinal anæsthesia which have been reported have been in patients of an age which renders it likely that they were suffering from this disease.

The point on which I am anxious to lay the greatest stress is that the vomiting, lividity, and sweating are in the main due to poisoning by the anæsthetic agent which is absorbed vià the cranial venous sinuses into the general circulation and so produces far-reaching effects. To ensure the safety of the procedure we should endeavour to limit the action of the anæsthetic agent to the vertebral cavity; this Mr. Barker has shown us how to do by employing gravity. We must further prevent the absorption of the drug by keeping it in

⁷ Löffler: Münchener Medicinische Wochenschrift, 1906, p. 95.

the spinal theca, where, as has been stated, practically no absorption takes place; to do this the diffusibility of the fluid must be reduced to a minimum, and then absorption cannot take place to any extent. Further, means must be adopted to eliminate the conditions previously referred to as favourable to the absorption of fluid from the cranio-vertebral cavity—that is to say, the cerebral venous tension should be maintained equal to, or above, that of the cerebro-spinal fluid, and the arterial pressure should also be kept as near normal as possible. For this reason, in addition to those previously given, I think it wise to draw off more fluid than is injected and to give the solution in small bulk so that the tendency for absorption to take place is diminished.

These views receive support from the fact that, as Dr. Hill states, when saline coloured with methylene blue is injected it can be found in the stomach and bladder in from 10 to 20 minutes; this, in fact, is the exact time at which symptoms of poisoning assert themselves under spinal anæsthesia. In my second series of 100 cases, therefore, I have made an effort to control and localise the effects of the injection by employing a fluid the diffusibility of which is low and the specific gravity of which can be increased to the required amount vithout altering the depression of its freezing point. Now Tuffier's believes that the toxicity of cocaine and its derivatives depends on their relative diffusibility in cerebro-spinal fluid and that the clinical phenomena described indicate a slight toxic action on the nuclei of the

⁸ Wiener Klinische Therapeutische Wochenschrift, 1905, vol. xii., p. 373.

bulb. I think this direct action of the drug employed may be the explanation in a small percentage of cases and may possibly account for the various ocular paralysis reported from time to time. Tuffier states that stovaine does not diffuse since it is precipitated in the "exceedingly alkaline cerebro-spinal fluid." Now cerebro-spinal fluid is usually neutral, at least it was proved so when I had it tested fresh, but on standing it becomes alkaline owing probably to the oxidation of the urea. That a change does occur on mixing the two fluids is certain, but the action of the stovaine is not thereby impeded, as I have proved by injecting myself with stovaine which had been standing with cerebro-spinal fluid. There is also no proof that stovaine does not diffuse in cerebro-spinal fluid; indeed, there is evidence to the contrary, for Tuffier himself states that in using a 12 per cent. solution in two cases he produced symptoms which he attributes to diffusion, and rightly so. The diminished toxicity of stovaine is due, no doubt, to the fact that it is very slowly diffusible, and this property is accelerated by administering it with diffusible fluids and retarded in the presence of indiffusible fluids. I have acted on these views in my second series of 100 cases, and the results, I think, amply justify the views expressed.

Stovaine has been preferred as the anæsthetic agent for the reasons already mentioned, while, in order to facilitate localisation by gravity, an indiffusible vehicle had to be found with which stovaine is miscible. Dextrin was chosen as the most suitable substance, for it is readily soluble in water, can be employed in any strength, and is innocuous to the tissues. The specific gravity of such a fluid can be raised or lowered at will without affecting the diffusibility of the solution. Normal saline is also used in strength isotonic with cerebro-spinal fluid, for it has been shown that though the diffusibility of dextrin-stovaine solution is above that of cerebro-spinal fluid when estimated in relation to water, yet when introduced into cerebro-spinal fluid changes take place which make its diffusibility considerably less than laboratory experiment indicates. The diffusibility of the stovaine is further delayed by the dextrin solution, which is viscid enough to prevent the former mixing to any great extent with cerebro-spinal fluid.

If Table II. be referred to it will be seen that 14 cases were anæsthetised with the stovaine-glucose solution for comparative purposes, and that the remainder of the children were injected with dextrin-stovaine solutions in eight different proportions. The results are tabulated so that comparison is easy, but some explanation of the figures is necessary as the most striking results are there very imperfectly represented.

T. WILLIAM											

It will be seen that there were two failures to produce anæsthesia; one of these children had spinal caries and only the perineum and sphincters were affected. Therefore there was one failure due to technique.

General anasthesia was employed in nine cases, and this is no discredit to a method which was on trial and the behaviour of which was unknown. In five of these cases (laparotomies) the anæsthesia was complete and perfect, but did not last long enough because the bulk of fluid administered was not sufficiently large. In three of these five cases only a whiff of chloroform was administered for the final suture. In adults this would have been unnecessary, but in children operation under spinal anæsthesia is impossible unless there is a complete flaccid paralysis, for they resent the presence of any of the sensations; that is to say, either analgesia or diminished painful sensation alone is insufficient in the great majority of cases. Two of the remaining cases (herniæ) required general anæsthesia, since the effect of the stovaine passed off too early. In one further laparotomy spinal anæsthesia was administered up to the umbilicus, and general anæsthesia was only resorted to when further work was found to be necessary in the upper abdomen. In only one instance was general anæsthesia necessary for operation owing to presence of deep (bony) sensation, and in this case the technique was probably at fault. It is clear, therefore, that in seven of the nine cases the short duration of the anæsthesia entailed the use of chloroform or ether, while in two cases only was this demanded by an imperfect result.

In this connexion three important facts are evident:—
1. That for abdominal work the bulk of the fluid given must be increased above that necessary for the lower limbs, if the duration of the anæsthesia is to be sufficient. 2. The greater the proportion of dextrin present in the solution, the shorter will be the period of anæsthesia. This fact is well illustrated in Table II., column 5. 3. In many of the cases in this series a high puncture (between the first and second lumbar spines) was practised, and the amount of fluid injected was small; the result was a uniformly short anæsthesia. A longer effect is obtained with a lower puncture and the injection of a large bulk of the solution.

In columns 6 and 7 of Table II. are further recorded the longest and shortest times: the discrepancy appears greater at first sight than is really the case. The majority of instances of short anæsthesia were in abdominal work at a time when the factors influencing the duration of anæsthesis were not sufficiently recognised. A perfectly satisfactory result in this direction has only been achieved quite recently in my third series of 100 cases now nearing completion.

The second section of Table II. indicates the relation of dose to the duration of anæsthesia. A glance at the figures shows clearly that, speaking generally, the larger the dose the longer the duration. Fluid B (Table II.) does not bear out this statement, owing in all probability to the small number of cases. Fluid B2 appears contradictory because in the 43 minutes group of cases there were three laparotomies in which high puncture and small bulk of fluid was the practice adopted. There was only one such case in the 54 minutes group. The factors influencing the duration of the paralysis have, I think, been sufficiently investigated to permit the assumption of definite rules in accordance with the foregoing statements.

The third section of Table II. deals with complications and sequelæ attendant upon the employment of spinal ancesthesia and shows striking results consequent on the injection of fluids of diminished diffusibility. These results

have been, in fact, infinitely better than the figures indicate and some amplification of the recorded facts is therefore The first three columns of this section deal with vomiting and retching during and after operation. It will be seen that nine cases vomited during the operation. Two of these vomits (Fluid Λ) were in the same child and occurred almost immediately after puncture, so that neither of them should be included in a comparison with the first series of cases, since on neither occasion was it the precursor of toxemia, which the table shows to have been completely absent. With Fluid B two vomits are recorded, of which one should be eliminated, since it occurred after the first injection of stovaine which failed to reach the subarachnoid space, produced no paralysis, and was therefore probably absorbed into the blood-stream with increased rapidity. No vomiting resulted from the second injection, which gave a satisfactory anæsthesia. This phenomenon has been noticed on several Spinal anæsthesia should again be exonerated occasions. from causing the vomiting in one case with the use of Fluid B1. This child was nearly moribund from intestinal obstruction due to abdominal tuberculosis. The first injection failed to reach the subarachnoid space, with the usual result that vomiting ensued. The child received two more injections for an operation which lasted one and a half hours, but no further vomiting resulted and her condition did not deteriorate at all. Two of the vomits further occurred with stovaine-glucose solution. It is fair to say, therefore, that with dextrin-stovaine solution three cases vomited during operation, as against 21 cases in the first series. Still more striking is the result when it is borne in mind that the vomits in the second series were very small. Usually there was one vomit producing one or two drachms of fluid which, as often as not, represented some brandy or milk administered on the table, and was in no way comparable with the copious or repeated vomiting in the first series.

Retching during the operation is seen to have become more frequent as the stovaine in the fluid used was increased and the quantity of dextrin diminished. This factor, however, is not alone concerned in the causation of this symptom. No doubt the retching is in part attributable to the increased diffusibility of the solution as the dextrin is diminished, but evidence has since been forthcoming that even when this factor is eliminated the symptom may be present and in no way connected with signs of toxemia.
This retching nearly always amounted to one or two spasms rarely lasting more than from 10 to 15 seconds, and occurred for the main part with a high anæsthesia. The explanation is, I think, that upon the sudden paralysis of the lower intercostal muscles there follows a compensatory over-action of the diaphragm which presses on the stomach and for the moment causes retching; this symptom almost immediately passes off as the body becomes accustomed to breathing almost entirely diaphragmatic. I have further noticed that under high anæsthesia the stomach is nearly always somewhat distended; and, if this is the case, there would be an additional reason for the patient resenting in this way any sudden over-action of the diaphragm. If these views are correct, occasional retching is an event which will always have to be reckoned with in high spinal anæsthesia.

A diminished amplitude of respiration consequent on a high paralysis must necessarily cause a slight change of colour; this I have called in Table II. "respiratory pallor." In these cases the lips retain their good colour, the eyes do not become sunken, nor is there any sweating, all features so prominent in toxic cases. Another factor in the production of "respiratory pallor" is the loss of heat from the paralysed area, which is often cold to the touch when the unaffected area is quite warm; between these two there is usually a sharp line of demarcation. This slight loss of colour occurred nearly always with high anæsthesia and was often so slight as to be noticeable only to one watching for the change, while the colour was always rapidly restored on disturbing the child in any way and causing it to take a deep inspiration, for it will be remembered that many of the children sleep during their operation.

Quite a different and unmistakeable feature is the livid pallor due to stovaine poisoning such as was recorded in the first series and which did not yield to the same measures. Of these there were no examples with dextrin-stovaine solution and one where adrenalin was employed. The columns showing vomiting after operation and headache are instructive, for if a study be made of these sequelæ (which

on every occasion were very slight) it will be evident again that dextrin delays absorption to a considerable extent; thus when symptoms are not present during operation the stovaine is absorbed so gradually that its effect is not manifest in the system until the same night or the following day. In support of this view is the notable feature that children usually have a temperature of 100° to 103° F. after a spinal injection of dextrin-stovaine solution (on one or two occasions the temperature reached 104°), while in the first series when the disturbance on the operating table was very much greater, there were very rarely any after-effects, and it was unusual for the temperature to rise above 100°, if as high. The temperature invariably fell to its usual level in about 24 hours.

Finally, Table II. shows that Fluid A, containing the highest proportion of dextrin, proved to be the most satisfactory from the point of view of the prevention of toxemia but least satisfactory as regards the duration of the anæsthesia.

Efforts to keep the high proportion of dextrin in the solution and at the same time to prolong the anæsthesia have only recently proved completely satisfactory, as I hope to show in the publication of my third series of 100 cases.

Advantages of the solution.—1. Diminution of the amount and rate of absorption of stovaine into the blood-stream with the attendant symptoms of poisoning.

2. Accurate localisation.—A perfect control over the distribution of the paralysis by the aid of gravity is possible. The higher the proportion of dextrin in the fluid the more definite is the line of demarcation between the paralysed and unaffected areas. This line corresponds to a definite segment of the cord. If the paralysis be limited to the tenth dorsal segment the lower half of the abdomen can be seen to be completely paralysed and "blown out" during any expiratory effort, while the upper halves of the recti abdominis are rigid and contracted.

By using a small bulk of fluid and making a high puncture I have succeeded in producing a perfectly operable anæsthesia of the abdomen while movements of the feet and legs were still under voluntary control. These phenomena have been demonstrated on more than one occasion, though such a performance, while demonstrating clearly the value of gravity as a localising agent, is of no value in operative surgery.

3. The paralysis is absolute. There is no question that only analgesia is produced or indeed that any of the sensations are preserved. I am greatly indebed to Dr. F. E. Batten for so kindly testing the nervous phenomena for me in these cases. Dr. Batten's results clearly prove that all nervous communications between the paralysed and healthy parts of the body are cut off, and I will briefly give an account of two cases in this series.

CASE 1. Right inguinal hernia.—2.15 p.m. First injection; incomplete. 2.45 p.m., second injection. 3 p.m., complete ansesthesia to second dorsal segment. 3.30 p.m., no return of sensation. 3.45 p.m., some return of painful sensation to middle of thigh. 3.55 p.m., movements of legs began to return; no sense of position; knee-jerks still absent. 4 p.m., knee-jerks returned; sense of position in big toe; painful sensation still absent below knees; muscular power fairly good. 5 p.m., complete return.

aation still absent below knees; muscular power fairly good. 5 P.M., complete return.

CASE 2. Tendon lengthening.—3.30 P.M., puncture. 3.40 P.M., anæsthesia over legs; still feels heat and cold; sense of position still preserved in big toe. 3.45 P.M., operation; complete anæsthesia to seventh dorsal segment; knee-jerks absent; complete motor paralysis.

4.7 P.M., still complete anæsthesia. 4.15 P.M., no change. 4.20 P.M., some return of heat; cold and painful sensations over abdomen. 4.30 P.M., movements returning in legs (proximal slightly before distal); no return of sensation in legs; no sense of position; knee- and anklejerks still absent. 4.45 P.M., still anæsthetic below knee; no sense of position. 4.50 P.M., return of sense of position in knees. 5.0 P.M., return of sense of position in knees.

These results are interesting, particularly as, from the practical point of view, they illustrate the following remarks: (a) the anæsthesia by being absolute practically eliminates surgical shock; and (b) the return of motor power before sensation gives sufficient warning that the anæsthesia is passing off to enable preparations to be made for a second injection to be given if necessary.

4. A further testimony in favour of using this solution is found in the following patient anesthetised with A solution. A girl, aged seven years and two months, had been operated on under spinal anæsthesia with stovaine-glucose solution on two previous occasions, and with each injection showed symptoms of stovaine poisoning—namely, vomiting, retching, pallor, and sweating. The doses used were 2.5 and 3.0

centigrammes of stovaine. On the third occasion 2 cubic centimetres of A fluid (or 5 centigrammes of stovaine) were injected and a perfect paralysis, the level of which was limited sharply to the costal margin, was obtained. The child was perfectly comfortable and did not change colour at all, while there was no vomiting, retching, or sweating. I only mention this case, though there are other striking examples of the improvement obtained in the second series.

In conclusion, a word must be said regarding the advantages

of spinal anæsthesia in the surgery of children.

1. Advantages to the patient. - When the anæsthesia is absolute, and this is essential in operating on children, surgical shock is abolished, for there is no transmission of impulses from the lower to the upper neurons, since these impulses are cut off at the posterior roots in each segment up to the limit of the paralysis. Further, the return of function in the paralysed parts is so gradual (vide supra) that delayed shock has rarely been encountered. For these reasons surgical measures in children assume a far wider scope, and there is no necessity for hurrying over operations on the abdomen, bones, and the larger joints. The two lists of operations reported embrace such a variety of cases that there has been ample opportunity of judging the relative merits of general and spinal anæsthesia. further consideration is that the anæsthesia is (or can be) strictly local and almost limited to the part to be operated on, so that the higher centres, lungs, &c., escape any interference, and such sequelæ as pneumonia, acute bronchitis, acute and delayed chloroform poisoning, and perhaps, also, the onset of acute pulmonary tuberculosis need not cause the surgeon any apprehension. Also the risk of sudden deaths from "status lymphaticus," which always come as

such an unexpected blow to a surgeon, is abolished.

2. Advantages to the surgeon.—These are particularly the ease and comfort with which grave operations can be performed without the distraction of considering the depth of the anæsthesia or the personal equation of the anæsthetist, for the anæsthesia is reduced to an almost mechanical certainty and the number of ordinary assistants is reduced. The absolute muscular relaxation obtainable without endangering the higher centres makes manipulations infinitely easier. For instance, it is only necessary to operate on an intussusception under general and then under spinal anæsthesia to appreciate the advantages of the latter in acute abdominal work. Thus a smaller incision permits of equal access to different parts of the abdomen, since the muscular relaxation permits the opening to be pulled over to almost any position, and for the same reason there is nothing approaching the same tendency for distended intestines to protrude from the wound. Operative technique is thereby much simplified and the gain in time is very striking. In operations on fractures, also, the difference in the ease with which reduction and accurate apposition can be effected saves a great deal of the time and violence necessary under general anæsthesia. 10

With the exception of one case of resection and anastomosis (and this child, aged eight months, died four hours after operation) no case of intussusception has been lost under spinal anæsthesia, one case of appendicitis with practically general peritonitis has died on the eighth day, and only one case of general pneumococcal peritonitis (other than pyæmic) has been lost up to the time of writing. The results of former years compare very unfavourably with

Advantages subsequent to operation.—Vomiting in acute abdominal disease, after relief by operation under spinal anæsthesia, is practically unknown, and this symptom is, in my experience, one of the most important factors in producing an unfavourable result.

Pain, even after the most severe operations, is so slight that it is very rarely necessary to give any hypnotics at all, and if these are required a minimal dose always suffices. As an instance of this let me quote the case of a girl, aged six years, whose leg was amputated through the thigh. She was given no drugs after the operation, and it was only after two days that she discovered the loss of her leg.

Children are given food, except where contra-indicated, immediately on their return to the ward if they want it, and the constant attention of special nurses is not required during the recovery from rachi-stovainisation. No death in this series has resulted from spinal anæsthesia, and as regards

sequelæ there have been none; therefore, seeing that the children operated on are, for the most part, frequently under observation afterwards, this fact speaks well for the method. Much improvement has been made and some interesting results have been obtained during the performance of my third series of cases, the details of which, however, must be postponed until a future occasion.

Since writing up my cases I have seen an article written by McGavin and Williams ¹¹ from the Seamen's Hospital, Greenwich. Their results correspond very nearly with those in my first series, anæsthetised with the same solution, with the exception perhaps of a larger percentage of cases in their series in which some pain was felt during operation. This pain would have necessitated the use of chloroform in a much larger number of cases had the subjects been children. For details I would refer the reader to their valuable record.

I wish in addition to thank the members of the surgical staff at Great Ormond-street for the numerous opportunities they have so kindly afforded me, and especially Dr. F. E. Batten, Mr. G. E. Waugh, and Dr. H. Thursfield, for their advice and assistance.

Great Ormond-street, W.C.

Clinical Rotes:

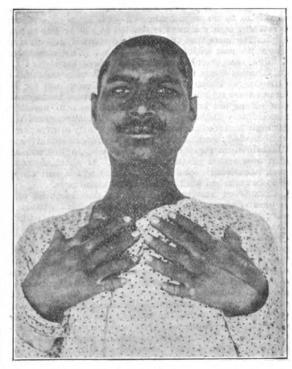

MEDICAL, SURGICAL, OBSTETRICAL, AND THERAPEUTICAL.

A CASE OF MEDIAN HARE-LIP ASSOCIATED WITH OTHER MALFORMATIONS.

BY E. OWEN THURSTON, M.B., B.S. LOND., F.R.C.S. ENG., CAPTAIN, INDIAN MEDICAL SERVICE.

THE acknowledged rarity of median hare-lip is my reason for publishing this case.

The patient, a Hindu, aged 20 years, a recruit for the Bengal police, was brought for medical examination. Besides the hare-lip it was also noticed that he had six fingers on

Median hare-lip in a subject with six fingers and six toes on

each hand and six toes on each foot. The hare-lip, as will be seen from the illustration, is exactly median and extended to just beyond the red border. The palate was normal.

The supernumerary digits were symmetrically placed on the ulnar borders of the hands; each possessed a metacarpal bone but only two phalanges. The extra toes were also symmetrically placed on the outer borders of the feet and possessed a metatarsal with two phalanges each.

No history could be elicited of any malformation in the parents or elder relatives of the patient, but a younger brother, aged five years, possesses seven fingers on each hand, six left toes, and the normal number on the right foot. This brother had also a median hare-lip exactly similar to the one now described.

Gaya, Bengal.

CARCINOMATOUS GROWTH OF CÆCUM CAUSING INTUSSUSCEPTION AND INTESTINAL OBSTRUCTION; REMOVAL THROUGH TRANSVERSE COLON; RECOVERY.

BY HAROLD STIFF, M.B., B.C. CANTAB., M.R.C.S. ENG., L.R.C.P. LOND.,

SURGEON TO THE WEST SUFFOLK GENERAL HOSPITAL, BURY ST. EDMUNDS.

A WOMAN, aged 53 years, was admitted to the West Suffolk General Hospital under my care on July 15th for intermittent attacks of abdominal pain of a colicky nature, sometimes accompanied by vomiting and distension, with gradually increasing constipation and emaciation. A large, firm, painful, moveable mass could be felt in the right hypochondrium. The tongue was coated, the breath was foul, the temperature was 97° F., and the pulse registered 106. The patient was placed upon fluid diet and was given castor oil and saline aperients by the mouth and large rectal injections twice daily. Under this treatment the bowels were unloaded, the attacks of pain became less frequent, and the mass became smaller and softer and moved downwards towards the right iliac region. The tongue cleaned and became moister, and the patient was more comfortable. After a few days, however, symptoms of subacute intestinal obstruction recurred, the mass became larger and firmer, and moved upwards and towards the middle line. The attacks of pain became more frequent and severe, and the patient was unable to retain even liquid nourishment.

Operation.—The patient was anæsthetised by a mixture of chloroform two parts and ether three parts, and the abdomen was opened by a median incision extending from two inches below the ensiform cartilage to the umbilicus. The peritoneum was incised and the transverse colon, greatly distended, was found immediately beneath. This was lifted out of the wound and a large, solid, lobulated mass was felt inside of it. A longitudinal incision six inches in length was now made in the transverse colon and the mass was explored. It was found to be a carcinomatous infiltration of the cæcum, of the size of an orange, which had caused a progressive obstruction of the lumen of the bowel. The latter for the space of an inch or more from the ileo-cæcal valve barely admitted the passage of a person's little finger. The execum, carrying with it a portion of the ileum, had become invaginated into the ascending colon, forming an intussusception with its apex at the ileo-execal valve, the appendix lying between the entering and returning layers. The growth was gently drawn out through the incision in the transverse colon and was resected. The ileum was divided at the ileo-excal valve and the excum just above the orifice of the appendix. The cut ends of the ileum and the invaginated cæcum were next united by end to end anasto-mosis with a continuous Lembert's suture of fine catgut, the appendix was amputated, and the anastomosis was gently returned to the interior of the ascending colon, thus reducing the invagination. This was a matter of some difficulty on account of the cedematous state of the bowel. The longitudinal incision in the transverse colon was now closed with Lembert's sutures of fine catgut, the mesentery was drawn well over it, and the abdominal wound was sutured with silkworm gut, completing an operation which occupied one hour and 25 minutes. The preliminary treatment had completely emptied the bowel, and fæcal matter was never encountered. The patient left the table with a pulse of 130 and, though collapsed, rallied with the aid of saline rectal injections within 24 hours.

The after-history of the case was uneventful. The bowels acted in response to a turpentine enema, given to relieve flatulence, on the second day after the operation. On the seventh day solid food was allowed, and the patient left her

bed on the seventeenth day and the hospital at the end of four weeks.

My thanks are due to my colleagues, Dr. C. S. Kilner and Dr. J. S. Hinnell, at the West Suffolk Hospital, for their kind and skilful assistance during the performance of the operation, and to the house surgeon, Mr. A. D. Rope, for his excellent administration of the ansesthetic.

Bury St. Hdmunds.

A CASE OF HYSTERICAL DEAFNESS TREATED BY SUGGESTION.

BY P. MACLEOD YEARSLEY, F.R.C.S. ENG., SENIOR SURGRON TO THE ROYAL EAR HOSPITAL, SOHO; MEDICAL INSPECTOR OF DEAF SCHOOLS, LONDON COUNTY COUNCIL, ETC.

AND

H. E. WINGFIELD, M.D., B.O. CANTAB.

THE occurrence of true hysterical deafness is not common, and in the following case, although the treatment ultimately failed, the partial success which resulted from hypnotic suggestion makes it worthy of publication.

The patient, a woman, aged 37 years, was first seen at the Royal Ear Hospital, Soho, on May 7th, 1908. She had just returned from India, where she had been for 30 years, and stated that she had been deaf two years, the deafness coming on suddenly after the birth of her seventh child. Before this time she was subject to severe hysterical fits, lasting over an hour; during which she shrieked and kicked and became semi-maniacal. These fits recurred about every six weeks.

On examination both tympanic membranes were normal, the Eustachian tubes were free, and there was nothing noteworthy to be seen in the nose or throat. Functional tests gave the following results: The accoumeter was only heard when in contact with the mastoids. Rinné's reaction was negative on both sides. Bone conduction to C (128), — 15 seconds both. Galton's whistle, both sides nil. By air she appeared to hear from 3 C 16 to C¹ on both sides, C² and C³ were doubtful, C⁴ both nil. Placed on increasing doses of strychnine, she was again tested on July 3rd, and so unreliable were her reactions that it was probable that the results obtained on May 7th were quite erroneous. She said she could hear forks which were not vibrating, and vice versa. Valerian was prescribed, and on Sept. 3rd it was noted that she was beginning to lip-read unconsciously. On Sept. 24th when he stood behind her she held up her hand whenever he spoke.

The patient was finally placed under the care of Dr. Wingfield (after consultation with Dr. J. Milne Bramwell), who reports as follows: - "I first saw -– on Nov. 6th. 1908, and altogether saw her on nine different occasions, the last being on Dec. 30th. Though she was apparently quite deaf when I first saw her, her hearing returned for about two hours soon after she left my house, but her deafness then returned. On the third occasion she told me that she could hear me quite well, but that the moment she heard she forgot what I said. The result of the treatment was that she could hear fairly well when she left me on Dec. 30th. Since then I have heard from her husband, with whom she is now in India, saying, 'The improvement she made while under your treatment has gradually disappeared, and she is now in the same state she was in when you first saw her.' It was unfortunate that treatment had to be so very much curtailed owing to her having to go to India. While it is impossible to say that she would have been permanently cured, there can, I think, be no doubt that the relapse might have been considerably delayed.

The case well illustrates the absence of any signs of aural disease and the unreliability of functional tests in these conditions. A certain number of cases of true hysterical deafness are on record, but very few appear to have been submitted to careful and systematic testing. Suggestion has been known to be successful in some cases, and that under consideration certainly appears to have been one in which hypnotic treatment would have succeeded had not circumstances unfortunately prevented longer trial. An interesting phenomenon in the case was the patient's statement that "the moment she heard she forgot" what was said. It would appear as if there was some fault in the connexions of the auditory centre, possibly similar to that in the rare cases of "word-deafness" met with in children

Reviews and Notices of Books.

The Oxford Medical Publications: The Principles of Pathology.

By J. George Adami, M.A., M.D. Cantab., LL.D., F.R.S.,
Professor of Pathology in McGill University, and Pathologist to the Royal Victoria Hospital, Montreal; late
Fellow of Jesus College, Cambridge. Vol. I., General
Pathology, with 322 engravings and 16 plates. London:
Henry Frowde and Hodder and Stoughton. 1909. Pp.
948. Price 30s. net.

Or all the sciences ancillary to medicine there is none more interesting and more important than pathology, which is, indeed, the basis of rational medicine. A scientific and thoughtful treatise on this subject is therefore of the greatest value, and is an almost essential companion for the practitioner who desires to have a reason for the measures he adopts in treatment. It is a matter of some interest that the study of pathology, which was a potent factor in the genesis of the therapeutic nibilism so widely current in some schools of medicine during the latter part of the nineteenth century, should eventually have been the means of enriching us with methods of treatment which, though yet in their infancy, promise to be of far wider effect and greater value than drug treatment. This fact affords the best evidence that pathology has advanced beyond the study of morbid anatomy, and indeed beyond the study of the morbid changes in the cell histology so ably pioneered by Virchow. It has extended to the study of cellular function in disease and its disturbances. Professor Adami has special qualifications for writing an advanced treatise on pathology, since his experience is wide, his training has been catholic (he refers in his preface to his intimate association as a student with Milnes Marshall and Francis Maitland Balfour, Michael Foster and Rudolf Heidenhain, Julius Dreschfeld and Charles Smart Roy, Emile Roux and Elie Metchnikoff); moreover, he writes well, and though at times his subject matter is abstruse, he writes clearly and intelligibly, expressing his own opinions forcibly while giving due weight to the work of others, even when criticising them. We are not surprised from the magnitude of the work to learn that this book has been nearly 12 years in preparation, for there is nothing hasty or ill-considered about it.

Professor Adami begins his book by a general review of cellular physiology, considered from the standpoint of structure in relation to function, development, variation, and heredity, all being included under the general heading of prolegomena. It is this section which imparts a somewhat individual and original character to the book, and it is one which we may single out for special praise. We have read it with interest, and though Professor Adami's views on cellular functions are sometimes at variance with those of other authorities he is careful to indicate their tentative character. Having given a general résumé of cellular structure and function and of the chemistry of the cell he develops the conception of the biophore or ultimate molecule of living matter into a theory—the "biophoric theory"-which is applied to the explanation of growth and even to the complex processes of variation, adaptation, and evolution. The biophore is conceived as a ring of radicles, each having free affinities, which can be satisfied by taking up free ions from the surrounding medium, resulting in the formation of side chains. In the process of growth these side chains become built up into fresh rings to form new biophores. In this connexion the importance of enzyme action is discussed in some detail and the peculiar phenomenon of reversibility is described. Reversible enzyme action being regarded as a primordial function of living of Ehrlich's side-chain theory.

matter, the startling suggestion is offered that the free enzyme is the simplest manifestation of life. The ingenious applications of the biophore theory serve to bring out clearly the nature of some of the complex problems of biology and to give point to the vexed question of epigenesis and preformation and to that of the transmission of acquired characteristics. In this section Professor Adami also gives a clear account of the Mendelian theory of heredity and of the various forms of inheritance.

The second section is devoted to a critical and detailed examination of the causes of disease. After a general consideration of the inheritance of morbid and abnormal conditions, the causation of such as are of intra-uterine and parturient acquirement is discussed, followed by an interesting and exhaustive study of monstrosities and abnormalities. The theories offered to account for the occurrence of the various forms of monsters and teratomas are clearly described and a very good classification is given. The factors leading to the post-natal acquirement of disease are then examined, classified, and separately considered, separate chapters being devoted to non-parasitic and parasitic exogenous intoxications, protozoan and metazoan parasites, and the endogenous intoxications. The description of bacterial agencies as causes of disease, with the discussion of infection and of the normal defences of the organism, is admirably clear, and though concise, presents in a suggestive manner the general principles of infection, while indicating where our knowledge is as yet incomplete. general heading of endogenous intoxications the morbid conditions induced by disturbances in the internal secretions are described, and the importance of the hormones is indicated. The pathology of gout, diabetes, obesity, eclampsia, and acidosis are all considered, and the gastro-intestinal intoxications are separately described, since Professor Adami rightly maintains that these are, strictly speaking, exogenous, and should therefore not be included among the auto-An interesting discussion on overstrain and intoxications. disuse as predisposing factors in causing disease and of predisposition and susceptibility concludes this section, which we can thoroughly commend as a thoughtful and suggestive presentation of the etiology of disease.

The third section deals with the morbid and reactive processes, and is divided into two parts. The first treats of the morbid and reactive processes proper-i.e., inflammation or the local reaction to injury, the processes of infection or the systemic reaction to microbic injury, and the processes of immunity. The second part deals with the tissue and cellular changes. Professor Adami long ago established a reputation as an authority on inflammation, and the account he gives of this process is a model of lucid description and analysis. He traces the reaction to injury from the simplest cases in the protozoa to its most complex form in the mammal, and indicates clearly the special features characterising the process in the different varieties of acute inflammatory manifestations. In like manner the varieties of chronic inflammation are differentiated and their special features described. In an interesting résumé the main date regarding inflammation are summarised in clear and critical fashion. In connexion with the systemic reaction to microbic injury or infection, the characters of the febrile state are analysed, and its adaptive nature in regard to the development of antibodies is suggested. The difficult subject of immunity is dealt with in a series of chapters extending to 78 pages, and within this compass a wholly admirable account is given. The various forms of antibodies are separately considered, and the most important theories are discussed. Professor Adami regards all of these substances as enzymes, and on this basis suggests a slight modification

The second part of the third section deals with the tissue changes, and includes a comprehensive consideration of hypertrophy, regeneration, grafting, and metaplasia. The neoplasms are then studied at considerable length. Professor Adami gives a classification, which he has previously published elsewhere, of the ordinary tumours as distinguished from teratomata and terato-blastomata into "hylic," or pulp tumours, and "lepidic," or those derived from primitive lining membranes, these main classes being further subdivided. This classification, though scientific, appears to us to be cumbrous and not altogether convenient. The theories of neoplasia and of malignancy are briefly outlined and discussed. The forms of different cysts are described, and then accounts are given of the various regressive changes, including the degenerations. Chapters are devoted to a consideration of calculi, pigmentary changes, necrosis, and death. Appendices are given dealing with protein nomenclature and with recent work on intercellular substance, nucleolar matter, and the accessory chromosome.

We have read this volume with great interest, for it is catholic in its range and critical in its presentation of the many vexed problems in pathology. It is the most considerable work on general pathology which has appeared in English within recent years.

Lectures on Hysteria and Allied Vaso-motor Conditions. By THOMAS DIXON SAVILL, M.D. Lond., Physician to the West-End Hospital for Diseases of the Nervous System, &c. London: Henry J. Glaisher. 1909. Pp. 262. Price 7s. 6d. net.

The appearance of a volume on hysteria by an English author is very welcome. Especially is this the case when the volume under consideration contains no mere restatement of the views of foreign neuro logists, but is in itself a definite contribution to the study of la grande névrose. For some reason it is more in the realm of organic than of functional nervous disease that the enduring work of English medicine is to be found, and Dr. Savill is therefore to be congratulated on having produced so original a book on a subject to which an immense amount of attention has recently been directed, and which can boast of an ever-increasing literature.

In this volume are collected a series of lectures, most of which have already seen the light in THE LANCET and elsewhere, and the author craves the indulgent criticism of his medical confreres for the redundancies incidental to the clinical form of lecture; these are more than compensated for by the case in reading and realistic presentation of cases which the lecture method affords. A comprehensive survey is made of the common hysterical disorders of the motor, sensory, and vasomotor systems; hysterical mental conditions are reviewed; the psychology and psychogenesis of hysteria are discussed; the etiology, pathology, and treatment of the disease are examined in some detail; and a couple of lectures are devoted to the consideration of certain admittedly vasomotor disorders which, in the author's opinion, have an important bearing on the problem of hysteria. The reader soon learns that Dr. Savill has a thesis to maintain and elaborate, and it is handled with a wealth of clinical illustration. Briefly, it may be put as follows: the majority of hysterical phenomena (it is worth noting that the author does not say all) are dependent on a vascular, and therefore nutritional, change in the part concerned, and it is through the sympathetic system that this change is effected. If we take a typical instance of a hysterical fit we figure to ourselves some young woman who, under the strain of an emotional disturbance, suddenly becomes pale, faint, confused, sinks into a semi-conscious state, exhibits various motor phenomena, and gradually or quickly resumes her normal condition.

That some, if not all, of these symptoms are also common to disorders universally recognised as vaso-motor in origin is in the author's view of primary importance, and his inference is that the essential cause of a hysterical "faint" is instability of the reflex vaso-motor centres in the sympathetic plexuses of the abdomen. A sudden emotion produces a rapid dilatation of the splanchnic arteries, a rush of blood to the interior of the abdomen, and consequent cerebral anemia and pallor of the skin. Hence the "attack" or "fit." If we take more elaborate hysterical cerebral attacks, according to the author the same essential features can be detected, and therefore, however complex they may be, the mechanism of their production is the same. The sudden splanchnic dilatation causes "a vascular change in the brain, of sudden onset and transient duration not an embolism or hæmorrhage but an ischæmia or a congestion, attended perhaps by slight serous exudation, which passes off and usually leaves no trace behind it.' The difficulties in the way of acceptance of this theory are patent. It is altogether too diagrammatic for the multifarious phenomena of hysteria. It is at best based on an assumption for which no support worth consideration is forthcoming.

We need not follow the author through the whole gamut of hysterical symptoms in his endeavour to apply this theory of their genesis, but we may glance at a case of hysterical monoplegia of the left arm in a fireman who fell on his left shoulder and three weeks later had a hysterical seizure followed by complete flaccid paralysis and loss of sensation in the limb. A "splanchnic storm," occasioning a serious vascular disturbance of the brain, and leaving behind it damage to the cortical areas corresponding with the injured limb, is the explanation given by Dr. Savill, but he does not hesitate to remark the difficulty in understanding why the vascular storm should damage one spot in preference to another. Among some six "localising factors" that he specifies are the reflected effects on the brain of a severe injury to the shoulder-joint and the impairment of the nutrition of the "ideo-muscular centres" of the limb as a result of its rest in a sling for three weeks before the hysterical seizure. But it may be remarked that the other factors that are mentioned are scarcely applicable in the present instance, and the above are obviously inadequate. Further, that a single "vascular cortical lesion" should produce the combination of complete motor palsy with complete insensibility to all forms of stimuli over an area embracing the limb and sharply limited by a line encircling its root is more than questionable. Even were the lesion of such a description we have no reason to suppose it would be of necessity situated in the "cortical ideo-muscular centre" for the limb, whatever that mean and wherever it be.

Dr. Savill frankly admits the possibility of other explanations, and while he criticises adversely the view that transfers the seat of the disease to a higher level he makes the not altogether unexpected statement, in italies too (p. 185), that "no single lesion or hypothesis in my judgment is capable of explaining all the various symptoms of this protean and strange disorder." This being the case, we cannot hope to find in the vaso-motor hypothesis the "open sesame" to the mysteries of the major neurosis and need not emphasise its insufficiency.

There is much in the volume that is worthy of study nevertheless, and the author has done a service in drawing attention to the frequency with which vaso-motor disturbances accompany the phenomena of hysteria. In more than one passage Dr. Savill hints that defective function on the part of spinal cord centres is at the root of some hysterical symptoms, and this deserves careful consideration. The book is eminently readable; its methodical arrangement

and lucidity of style enhance the interest of its subject. The chapter on treatment is replete with the practical suggestiveness that comes from experience.

A Practical Treatise on Disease in Children. By EUSTACE SMITH, M.D. Lond. Third edition. Edinburgh and London: William Green and Sons. 1909. Price 21s. net. Pp. 833.

THE third edition of Dr. Eustace Smith's work on the diseases of children is, as its full title indicates, a practical treatise; indeed, its ample roll of pages is almost exclusively reserved for the clinical aspects of this special branch of medicine. Although a considerable amount of new material is incorporated in the work, the original size of the previous edition is closely maintained by a compensatory abridgement of details relating to pathology and morbid This method of handling the subject will doubtless be appreciated by practitioners and others who refer to the work for the purposes of diagnosis and treatment, but it will necessarily deprive it of an extensive patronage among students who are preparing for their professional examinations. Those who are familiar with, and are appreciative of, Dr. Smith's work and teaching will perhaps be disappointed that he has given the reader so little benefit of his knowledge of the special subjects in the domain of peediatrics in which he undoubtedly excels-namely, in the uses of drugs and in the management of the infant's dietary. At the present day there are few greater masters of prescribing than the author of this book, but we look in vain for complete formulæ or a list of prescriptions in the form of an appendix. Of the indications for the use of special drugs there is ample information, but the reader is left to his own imagination as to the best manner of prescribing or combining them. We notice, however, that when the dosage is given, it is often almost heroic in amount. For instance, belladonna is recommended in doses of from 10 to 20 minims of the tincture for a child four years of age, and Fowler's solution in 10-minim doses for a child of the same age, while for an infant of 12 months it is stated that one drop of laudanum is not too large a dose. In these days of sero-therapy and hygienics the tendency is to discount the value of drug treatment, but if such drugs as belladonna, arsenic, and opium have any value at all opportunity should be given to get the full effect. That belladonna is now so little used in the treatment of enuresis or arsenic in the treatment of chorea is no doubt largely due to the fact that the young practitioner has not the courage of his opinions and employs his drugs in needlessly small doses; he will be well advised to study Dr. Smith's methods carefully. Though doubtless the reader will know well to what other of the author's published works he must refer for the required information, he must be prepared to seek in vain for enlightenment on the subject of infant feeding, except in the section which deals with infantile atrophy.

In a work which is so straightforward and free from controversy or speculation there is necessarily little to criticise. Indeed, the author seldom expresses an opinion unless he is sure of his ground; in fact, in a few instances his timidity in this respect lays him open to the reproach of facing both ways. For instance, on the subject of the first dentition, while he appears to be careful to respect the opinions of those who deny that teething is accompanied by pathological manifestations, he makes a concession to those who think differently by admitting that fever may result from this physiological process, and further, that the feverish child is eminently liable to fall a victim to the agencies which produce trouble in the digestive system. Surely the direct route is quite as good an explanation as this indirect

pathogenesis? Moreover, on p. 285 we notice the statement that inflammation and swelling of the gums during the cutting of a tooth may be a reflex cause of convulsions. If convulsions and fever are caused by dentition, why not other and minor evils? We are no more enamoured of the author's explanation of enuresis or incontinence of urine, which maintains that the condition is due to excessive irritability of the muscular fibres of the bladder. Usually this symptom is ascribed to nervous causes. Moreover, it is hardly logical to speak of infants acquiring the condition. All infants are more or less born with it, and they only lose the habit as the nervous mechanism which controls the function of the bladder develops and acquires stability. These, however, are very minor blemishes in a work which is so highly accurate and so well fitted for the purpose it is intended to subserve.

LIBRARY TABLE.

Outlines of Physical Chemistry. By GEORGE SENTER, Ph.D., B.Sc. Lond. London: Methuen and Co. 1909. Pp. 369. Price 3s. 6d.—In no other branch of chemical science has greater progress been made than in that known as physical chemistry, for not many years ago the subject was rarely included in any curriculum. Yet it concerns, however, very intimately some of the problems of medical science, and especially that part of the subject relating to functional activities. Bio-chemistry, in fact, has received its greatest impetus from a study of physical chemistry, in proof of which mention need only be made of such matters as osmosis, dissociation, electrical conductivity, law of mass action, equilibrium, all of which receive careful attention in the book before us. Primarily intended as an elementary introduction to the subject, it yet covers a good deal of ground, and the author's experience as a teacher has opened his eyes to the requirements of the beginner. His method of teaching, for example, by giving numerical illustrations of those laws and formulæ which present difficulty is sound, and he has been wise, further, we think, in using, as far as the treatment of such a subject permits, only the most elementary mathematics.

Hygiene for Nurses. By ISOBEL MCISAAC, formerly Superintendent of the Illinois Training School for Nurses. New York: The Macmillan Company. 1908. Pp. 208. Price 5s. net.—The instruction and training of nurses are now placed on a much more advanced footing than formerly. A nurse is now encouraged to take an intelligent interest in her work and to avoid becoming a mere machine; for this purpose, at most hospitals lectures are given by members of the medical staff and by matrons. In addition textbooks on nursing are now numerous. It is also essential that a nurse should know something about the elementary facts of hygiene. In this work the needful instruction is given in a simple and explicit manner, though it does not pretend to be more than a "compilation" intended to secure for the "young nurse a text-book on hygiene which shall be practical and within the range of her daily work." The chapter on "Food" gives many hints on the nature and amount necessary in health of the different varieties of diets. The remarks on adulteration of food are perhaps too discursive for a nurse, but nevertheless they will be found interesting. The observations on ventilation, heating, and lighting are concise and practical. The chapter devoted to a brief consideration of soil and water is also well written, and especial attention is drawn to the domestic purification of water. Some of the best chapters in the book are those on personal, household, and school hygiene-subjects which should be of interest to all nurses. We recommend this volume to its intended audience.

Intemperance. By the Right Rev. H. H. PEREIRA, Bishop of Croydon. London: Longmans, Green, and Co. 1909. Pp. 173. Price 2s. 6d.—This volume is one of the excellent series entitled "Handbooks for the Clergy," a series which is under the general editorship of the Rev. A. W. Robinson, the Vicar of All Hallows Barking. Dr. Pereira points out that the first edition of his book was published only some four years ago, but that within the interval between that edition and the publication of the second our knowledge as to the effects of alcohol has increased so widely that much new matter had to be added. We are so accustomed to wild and intemperate statements in temperance literature that we must congratulate the Bishop of Croydon upon the moderation which he shows forth. Of the evils of intemperance, not only in alcohol, we can confidently say that no profession. not even the clerical, has a wider experience than the medical. If intemperance disappeared, not only would crime diminish enormously but also sickness and a large amount of physical deterioration. But those interested in temperance may take courage from the fact that within the last 30 years there has been a wonderful improvement in the habits of all classes as regards alcoholic indulgence. Still, much remains to do, and Dr. Pereira's suggestions and descriptions of what is being done and what can still be done in the way of reform are sound and practical. One passage, however, shows undue optimism. In the chapter entitled "The Waste of Intemperance" Dr. Pereira gives some figures from a pamphlet published by the Church of England Temperance Society. There is a calculation by Mr. Arnold White to the effect that if the ordinary labourer were to give up one pint of beer per diem out of the three and a half which he is estimated to drink and were to invest the proceeds at 4 per cent. he would in 20 years' time have put by £135 17s. $3\frac{1}{2}d$. We have not checked the calculation, but we should like to know where the labourer could get a safe 4 per cent. for his savings, and what investments he is to choose which might not undergo some sudden and serious depreciation. We are glad to see that Dr. Pereira mentions the public-house trust companies, for to our minds the experiment which is being tried by these bodies is one that should give good results. chapter upon Personal Responsibility, with which the book concludes, Dr. Pereira quotes the following words of Professor Attwater of the Wesleyan University "in America" as to total abstinence. He adds that they exactly represent his views, and we may add that we agree with them also. "It is neither just nor wise to teach that the doctrine of total abstinence rests upon undisputed principles of either theology or morals. It seems to me that the question whether a man should be a total abstainer depends upon two considerations - his own welfare and the influence of his example." These are sound words. Perhaps we may be permitted to suggest to Dr. Pereira that in future editions he should give his references more fully than he has in the book before us. For instance, "Sir George Balfour, M.D., has said," is not of much assistance to one who wishes to pursue farther the remarks of the writer quoted, and we may say the same thing of the words of Professor Attwater. "The Wesleyan University in America" is vague.

Nahrungsmittel-Tabelle zur Aufstellung und Berechnung von Drütrerurdnungen für Krankenhaus und Praxis. Von Dr. HERMANN SCHALL und Dr. August Heisler. Würzburg: Curt Kabitzsch (A. Stuber's Verlag). 1909. Pp. 42. Price M. 1.90.—These tables, showing the composition of foods, were originally drawn up for use in the Medical Clinic in Marburg, and are specially designed for use in hospitals and for those practitioners who devote themselves to the study of diseases of nutrition. They will also prove useful

to the general practitioner. They consist of tables showing the composition of the chief foods used by man, including the relative proportions of proteins, fats, carbohydrates, common salt, and purin bodies present in these foods; also the amount of water and the heat value in calories of each food. These data occupy about 18 Four pages are given to the composition of mineral waters, many of which perhaps are not much known in this country, the ingredients being arranged as follows: common salt, sodium, potassium, and magnesium bicarbonates, sodium sulphate, magnesium sulphate, bicarbonate of iron, and carbonic acid. Lastly, the temperature of the natural waters is given. Then follow tables on the most important changes that foods undergo during cooking, and the amount of cellulose and mineral matter contained in 100 grammes of fresh uncooked foods. A table of the relative digestibility of foods and the time they remain in the stomach occupies one page. The remainder of the work is made up of tables showing the weights at different ages, the calorie-requirements in 24 hours under different conditions, and the average amount of protein required daily according to age. The work will prove useful to practitioners, while it is got up after the manner of a ledger, so that any item can easily be found.

Aids to the Analysis of Food and Drugs. By C. G. MOOR, M.A. Cantab., F.I.C., and WILLIAM PARTRIDGE, F.I.C. Third edition. London: Baillière, Tindall, and Cox. 1909. Pp. 249. Price 3s. 6d. net.—This is a capital little book and the authors may be congratulated on the success with which they have brought the third edition into line with new methods of analysis aimed at the detection of adulteration. What we appreciate most about it is that, while it gives a useful digest of most analytical methods worth applying, the chapter and verse are given of the original work upon the subject, so that if further details are required they may easily be found. As it is, the busy analytical practitioner will find in many cases sufficient material to help him to get the data he requires. We have gone through the sections carefully and have been impressed with the care that the authors have taken to present only those methods which have received recent approval. The sections demanding extension have received it, and burning questions, such as the non-existence of statutory powers to suppress the use of preservatives in foods (as recommended by a Departmental Committee), the extended analysis of potable spirits, the standardisation of drugs, receive adequate consideration and criticism. The exact references carefully given to the original papers on the recent important additions to analytical methods entirely exonerate the book from the opprobrium of being a cram-book or an insecurely "short cut" to knowledge.

JOURNALS AND MAGAZINES.

Edinburgh Medical Journal. - Three interesting articles appear in the September number of this journal. Dr. R. Dods Brown and Dr. R. Cranston Low report a case of pellagra in a patient who had never been out of Great Britain—apparently the second such case recorded. The subject was a woman, aged 21 years, who had never eaten maize but had consumed raw oatmeal and rice. Mr. D. P. D. Wilkie discusses Hirschsprung's disease or idiopathic dilatation of the colon and gives notes of five cases; he attributes the condition to over-distension of the colon with meconium in fœtal life, with resulting formation of a kink at the lower end of this part of the bowel. Dr. Peter Marshall deals at some length with the subject of lumbar puncture and describes a special needle adapted for the performance of this procedure. He enumerates the findings in the cerebrospinal fluid which are of diagnostic value and gives a long

3

list of conditions in which relief of symptoms may follow lumbar puncture.

The Dublin Journal of Medical Science.—In the August number Dr. J. Singleton Darling publishes a report on an outbreak of scarlet fever in Lurgan, in which the infection was apparently carried by milk and originated in the case of a child who had suffered from a condition not recognised as scarlet fever. Sir John W. Moore records a case of acute parotitis in the course of pneumonia, followed by recovery, and discusses the incidence of this complication in infective diseases. Dr. E. Hastings Tweedy continues his annual report of the Rotunda Hospital.

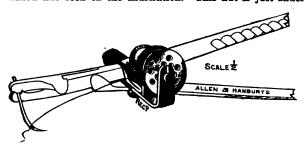

The Birmingham Medical Review.—The second of Dr. David Fraser Harris's lectures on the Essentials of Physiological History is published in the June number of this magazine, and deals with the subject of respiration and animal heat. In this branch of research British names are well to the fore, including, as they do, those of Boyle, Lower, Mayow, Hales, Black, and Priestley.

Rew Inbentions.

A SIMPLE SUTURE AND LIGATURE SPOOL-ATTACHMENT.

WITH the help of Mr. W. F. Chambers, of the Victoria Hospital, Folkestone, I have devised a suture and ligature spool whereby rapid and easy suturing and ligaturing can be accomplished.

The apparatus is a substitute for the more expensive "sewing machines" which have been devised from time to time, and consists simply of a light metal reel on a framework, which can be attached to most of the needle-holders in common use, or even to a pair of Spencer-Wells's artery forceps. The reel has deep flanges which are perforated, allowing for thorough sterilisation of its contents. Its axle is instantly unmountable from the frame, by half a turn of a milled nut seen in the illustration. This nut is just under

the thumb when working, and serves to control the rate of supply of suture material. A needle-half curved with an eye at the point—is the best to use in this contrivance; and, unlike the ordinary variety, once it is in the holder it need not be released. The needle is threaded as shown and then passed through the tissues in the ordinary way; the end of the thread is then gripped and held—in forceps—and the needle brought back along the thread, which is then cut between tissues and needle. This is one suture made, and the needle is ready for the next. It reads longer and more complicated on paper than it is, but actually the process is simple and rapid. A continuous suture can be adopted with slight modification, while for ligaturing the advantages are The whole attachment is cheap, adaptable, simple, obvious. clean, instantly changeable-allowing different efficient. materials or different sizes to be used-time-saving, and practical. It and its contents need not be touched at all after sterilising. A good all-round material to use on the spool is linen thread.

Messrs. Allen and Hanburys have most ably carried out the idea from my models and sketches.

Lies, Hants.

B. RICHARDSON BILLINGS.

Looking Back.

THE LANCET, SATURDAY, Oct. 1st, 1831.

A remedy has been employed by some, certainly of a most curious description, and well calculated to accelerate final dissolution. It is the belief of many persons that the cause of death by drowning is the impletion of the lungs with water; and knowing that fluids descend by their own gravity, they think that the most effectual method of evacuating the water is by suspending the asphyxiated person by his heels, not questioning but the remedy will be M. Louis is of opinion, that "they who are drowned inspire water, with which the air-vessels and cells are quite filled." But M. Detharding thinks quite contrary; he maintains "that drowned persons have no water in their chests, or air-vessels of the lungs, and that they perish suffocated for want of air and respiration, and that while the person is under water the epiglottis applies itself so closely, that not one drop of water can pass." I have already noticed M. Richerand's opinion, that the air-passages after drowning are found to contain a small quantity of frothy fluid; and that, if the body remain long under water, the spasmodic action of the glottis ceases, and that then water passes into the trachea and fills the lungs. Now M. Louis may be right, for the cases he has examined remained long under water; M. Detharding may be also right, for the cases he investigated may have been submersed only for a short time. But I think he is incorrect in assigning the close adaptation of the epiglottis, which is the coverlid of the glottis, to this aperture, as the cause which prevents the aqueous inrush to the lungs. It is true, in the act of swallowing, it is adapted, but I cannot agree with him that it continues thus applied:—"Anatomy," says Mr. S. Cooper, "proves the impossibility of its being so." M. Richerand appears to me to have given the most perspicuous account; I believe with him that the ingress of water is intercepted by the spasmodic constriction of the glottis, and not by the adaptation of the epiglottis; and that the water obtains admission after this constriction has, in consequence of the final extinction of vitality, ceased. In this case hanging by the heels could do no harm, but to make it a rule of practice cannot be sufficiently deprecated; for, in the first place, while constriction of the glottis continues, supposing water to have obtained forcible admission, the closing of the laryngeal opening would prevent its efflux; and, in the second place, the measure is highly detrimental, inasmuch as the congestion of the brain is augmented, a condition to which is attributable the suspension of animal life. Lastly, electricity has been employed for the purpose of restoring suspended animation. For my own part I dissent from its exhibition. The practice is condemned by Baron Larrey, and the rest of the French surgeons. "An atmosphere," says M. Richerand, "highly electrical at the approach of a storm, renders respiration very laborious in some cases." And I know a lady who was once the subject of chorea, who could always tell the approach of a thunderstorm, by the miserable feelings to which she was subjected by its influence upon her nervous system. We have seen that the electric fluid is a powerful agent in simultaneously arresting both organic and animal life. But it may be urged that the most deleterious substances, by judicious management, become most efficient restoratives in disease. This is granted, but who will define the due intensity of electric action that ought to be transmitted through a body in which vitality is all but extinct? 1

¹ Excerpt from Essay on Asphyxia. By John Thomas, Esq., Surgeon to the Dispensary, Well-street, Hackney.

ROYAL SOCIETY OF MEDICINE.—A meeting of the Therapeutical and Pharmacological Section of the society will be held on Oct. 5th at 4.30 P.M., when a discussion on the Teaching of Therapeutics in the Hospital Wards will be opened by Sir T. Clifford Allbutt. It is expected that Professor W. Osler, Dr. Harrington Sainsbury, Dr. J. Calvert, Dr. Robert Hutchison, and Professor W. E. Dixon will take part in the debate.

THE LANCET.

LONDON: SATURDAY, OCTOBER 2, 1909.

The Work of the International Medical Congress.

THE Sixteenth International Medical Congress, our report of whose labours was concluded last week, has proved to be one of the most interesting and successful of the many international congresses which have been held up to the present time. Every thinking mind must have considered the question whether, after all, the practical benefits resulting from international medical congresses are commensurate with the large amount of exertion, time, and money which must be expended in their preparation if they are to prove successful. Certainly it must be conceded that a congress in these days is not essential to the publication of new medical facts or theories. Without the aid of any such meetings all the advances in medicine and the allied sciences would quickly find their way to the uttermost parts of the earth by the channels provided by the medical press, so that if the sole aim and object of these gatherings were to be the diffusion of medical knowledge much less expensive and onerous methods could be readily pointed out. But congresses have another function than to diffuse knowledge; they should sift it and clarify it. Misunderstandings occur not only in the political world through want of personal knowledge of one another by the disputants, but in the medical world also. Scientific though the methods of any school of medicine may be, there is a possibility, nay, more, a probability, of misunderstandings arising between those who have never had an opportunity of conversing together, and year by year the difficulty of diverse tongues becomes less as the number of men increases who can understand and express themselves in two out of three great languages-English, French, and German. When scientific questions are made the subject of discussions in newspapers polemics may arise from some small and unimportant point; frequently the matter in dispute is enlarged by some extraneous force so that the field of battle is widened and the number of the combatants is greatly increased. is bad in ordinary matters, it is doubly regrettable in matters scientific, where no political or geographical landmarks should exist. Questions of priority of invention or discovery will always be arising and national pride may stimulate the quarrels attaching thereto. Theories evolved to explain the phenomena of nature and disease run some risk of being accepted or rejected rather because of the part of the earth whence they arise than because of their intrinsic value and of the firmness of the foundation on which they are built. The vex viva is ever more potent in promoting understanding and agreement than the written word. So for the prevention of these disputes and the elimination of bearers who come on to the field to carry off those

their causes no better machinery has hitherto been devised than such gatherings of medical men of all countries as the International Medical Congresses. We are not yet in Utopia and it would be unreasonable to think that international congresses can remove entirely all matters of dispute in the realm of medicine, but they should ensure that these disputes depend on an essential scientific difference of opinion, and not on the accidental point of the nationality of the disputants themselves. Differences of opinion must arise. It would be bad indeed for medicine if it were not so, for all new facts and theories must be tried on the touchstone of experience, by which alone can their real value be proved. The insight into the social life of other countries offered by international medical congresses affords a great opportunity for the test of practical knowledge; the value, for example, of hygienic regulations can only be gauged by inspection of the machinery and experience of the results. Thanks to the hospitality of each country where the congresses have been held, not only has good international feeling been promoted, but admirable chances have been given to the visitors to see the inner life of their hosts. When we regard international medical congresses from these points of view, as we should, we see that they are potent influences in civilisation, and this fact should make us overlook any muddle or waste of effort with which they may be connected in our minds.

It was obviously impossible for any journal to give anything like a full account of the proceedings of a Congress such as that at Budapest. When the transactions are published they will fill more than a dozen large volumes, and from this alone it is easy to see that even a résumé of the proceedings as a whole would be impossible in the columns of a weekly paper. We therefore selected for particular notice the proceedings of the last two sections as being concerned with subjects peculiarly suitable for discussion at international gatherings. These sections dealt with naval and military surgery, tropical medicine, and questions of quarantine, matters which concern all nations internationally. Every country at one time or another engages in war, and wise and humane as the world may be growing we cannot be supposed to have nearly outgrown the possibility of appeals to arms. Certainly at the present moment all Europe prepares more or less thoroughly for taking part in naval or military operations, and no one can feel certain that manœuvres may not be in a moment replaced by actual service; so that the questions connected with the hygiene of the army and navy in peace and in war, as well as everything connected with the surgery of naval and military operations, are subjects of paramount importance to all countries at this date. We therefore devoted no small proportion of the space allotted to our report of the Congress to publishing notes on these matters, and we may quote an instance in which the need for an international understanding in matters relating to military surgery is of vital interest. In all armies it is customary by different labels or "tallies" as they are called to indicate the condition of wounded men. If a man is slightly wounded he has a label of one colour, if he is seriously injured the colour is different, so that the

who have been injured are able to judge by the colour of the tally what to do with the patient. fortunately, there has been up to the present no agreement among different nations as to the use of these colours, so that a soldier may have a tally which to the bearers of one side would indicate that he is only slightly wounded and can walk, while to the bearers coming from the opposing forces the tally would indicate that he is seriously wounded and needs immediate operative treatment. Such confusion as this is unworthy of the times we live in, and we endorse the appeal made by Lieutenant-Colonel W. G. MACPHERSON, R.A.M.C., that an agreement may be arrived at as to the adoption of a uniform system of tallies. Other papers read in these sections included most interesting communications on prophylaxis against yellow fever, on the sanitation of ships, and on the Mussulman pilgrimages, an abiding source of danger to Eastern Europe. Complaint has been made that in many of the sections, even in those where matters of such general as well as vital interest were being discussed, the attendance was sparse, and that if it had not been for the presence of members anxious to read their own papers there would not have been an audience to whom the papers could have been read. It is unfortunate in some ways that this should be so, but a small debate well conducted by those of personal experience is of more value to science than a rambling discussion before a partially interested, though larger, audience.

It has been suggested that the present system of International Medical Congresses dealing with all branches of medicine and surgery will tend to come to an end and that we shall soon see the establishment of congresses dealing only with separate branches of medical science. We do not think such specialised meetings are likely to take the place of International Medical Congresses, though they may increase in number and do good work concurrently. The international meetings on dermatology have for more than 20 years proved the practical value of congresses dealing only with one subject; and congresses in hygiene, dentistry, and general surgery have also a record of success, especially the excellent International Congresses of Hygiene and Demography. But we feel that it would be a real loss to carry out to such a degree the idea of specialism that no general congresses should be held. There must always be this risk in specialism, that it may lead to too narrow an aspect of medicine among the practitioners, and this evil is averted by the mingling of the exponents of all departments of medicine at the various meetings of medical congresses. We do not ourselves see the signs, which are evident to some, that these general International Medical Congresses having served their purpose will soon cease to be held. This risk has been minimised by the establishment of a permanent bureau whose function it will be to remove all causes of friction, to make the assemblies as easy of approach as possible, and to prevent the waste of effort which is now so depressing to all concerned in these meetings. With the effective carrying out of reforms in organisation there will disappear the feeling that International Medical Congresses are, to word that feeling in the simplest way, more trouble than they are worth. This country has the honour of receiving the first international meeting of medical men to be held after the establishment of the permanent bureau, and those into whose hands the details of management will fall will have to bear a heavy responsibility. As the interval between the congresses has now been changed from three to four years we do not as a nation become the host of international medicine until 1913; but it is already not too soon to put in hand preliminary arrangements for ensuring that this country does full justice to the occasion.

The Empire and its Children.

If the topics selected by the writers of books may be regarded as straws indicating the prevailing directions of the currents of opinion, there is before us at the present time a satisfactory amount of testimony that the importance of children, when regarded as the adults of the near future and as the coming masters of the destinies of the Empire, is daily receiving an increased amount of consideration. It is daily more and more being recognised that if the United Kingdom desires to emulate the mother of the GRACCHI and to display her offspring as her jewels, she must at least submit these jewels to a considerable amount of polishing and of resetting before she can either look upon them with entire complacency as ornaments, or can regard herself, by virtue of possessing them, as in a position to speak without shame to her enemies in the gate. The recent publications of the Board of Education, and especially the timely and most valuable Syllabus of Physical Exercises, point to a degree of enlightenment, with regard to the view officially taken of schools, which almost amounts to a revolution, and which affords reasonable hope that these institutions, within a period of time negligible in the history of a nation, may really be made to afford to the young, in the well-known words of PALEY, "preparation for the sequel of their lives," even to the extent of defence against the wiles of the quack or the agitator.

Towards this good end many private influences and unofficial publications have been contributing; and we welcome among others an interesting volume on "Children in Health and Disease," 1 described by its secondary title as "A Study of Child-life," and written by Dr. DAVID FORSYTH, largely as an outcome of his experiences at the Evelina Hospital for Sick Children and at the children's department of the Charing Cross Hospital. Of the sources of his experience of healthy children we are not informed; but he has manifestly, either as a parent or in some other capacity, been an attentive observer of their ways and works, and has cultivated a sympathy with them which is essential to any correct understanding of their motives and feelings. On the other hand, he has attempted, we think, to cover too large a surface of ground, and has thus been compelled to deal somewhat superficially with topics some of which would have repaid a larger amount of care than has been given to them. More than once we have found, on the heading of a page or in an entry in the index, some promise which the text itself has only fulfilled in a way which makes us want more. With this qualification, we have nothing but praise for the

manner in which Dr. FORSYTH has traced out the gradual development of the intellectual faculties in the growing child, and it is assuredly only by attention to the natural history of this development that education, in the proper sense of the word, can ever be profitably conducted upon a large or national scale. In the cases of individual children there are, of course, infinite possibilities of influences calculated to counteract the blunders of the teacher; but when these blunders are crystallised into a system and supported by all the pressure of authority, their influence is certain to be disastrous upon at least a certain proportion of those who are rendered subject to them. The key to safety and advantage is to be found in the simple principle upon which we have more than once insisted, the principle that the development of the faculties of the growing organism is a physiological process, and therefore one which can only be conducted successfully under the guidance of physiological knowledge. The practical applications of this knowledge to every step of the educational process or period, to the regulation of sleep and food, to the character of clothing, to the division of tasks, to the duration of periods of application and study, to the arrangement of lessons in such a manner as to bring the more difficult of them within the periods of greatest functional activity, -such things and many others are dealt with by Dr. FORSYTH on a basis of principle resting upon knowledge; and his injunctions, in more than one particular, will be found to be in direct opposition to practices which have been rendered venerable by long usage, but which can no longer be defended, even upon the ground that they have been successful in their application.

This book may be fruitfully studied in connexion with another, on the higher education of boys in England, which has recently been published by Mr. CYRIL NORWOOD and Mr. A. H. HOPE, and which describes English schools, in respect of their success in imparting such education, as being "a hundred years behind France and Germany and forty years behind America," all of them, it may be observed, countries in which study of the immature organism has been taken as the only safe guide to endeavours to promote its development to the full measure of its potentialities. These outspoken authors condemn a large proportion of English schools utterly, as tested by the completeness of their failure to accomplish that which they are supposed to set themselves to do, and they point out that we alone among the greater European nations content ourselves with offering, instead of enforcing, inspection. There is no department of our public life in which the recent Royal injunction to "wake up" is more urgently required than in education; and because it is one which the average parent has never studied, and on which he is therefore incompetent, not only to advise, but even to judge of the character of the advice offered to him by others, it has become imperative that public attention should be directed to its character and its importance. No one can so far ignore the signs of the times as not to perceive many clouds on the imperial horizon, and the power of the children of to-day to deal with any tempests of which these clouds may be the harbingers will be materially conditioned by the red, and of high refrangibility as violet, and a tinge of these

character of the educational system under which they are now being prepared for the responsibilities of manhood and for the duties of citizens.

A Complete Theory of Colour-Vision.

WE publish in another column a paper by Dr. F. W. EDRIDGE-GREEN on the Theory of Vision which was read by him before the Section of Ophthalmology, and again by special request before the Section of Physiology, at the recent International Medical Congress at Budapest. No one who has studied the various theories of vision, and especially of its important adjunct colour-vision, can fail to be struck with the large amount of hypothetical material which has to be accepted to make them fit in with known facts. Dr. EDRIDGE-GREEN is striving to show that the older theories are no longer tenable, and that his view which he so fully and lucidly explains in his paper, and which was so enthusiastically received at Budapest, is capable of explaining every known fact relating to vision. We may sum up that theory as follows. When a ray of light impinges on the retina it liberates the visual purple from the rods, which then diffuses itself into the fluid surrounding the outer segments of the cones. In the fovea there is no visual purple until this diffusion takes place. This substance is photo-chemical and a photograph is thus formed. The rods are connected only with the formation and distribution of the visual purple and not with the conveyance of light impulses to the brain. The decomposition of visual purple by light chemically stimulates the ends of the cones, and a visual impulse is set up and conveyed through the optic nerve to the brain. Thus a colourblind person has an eye which in no way differs from the eye of a normal-sighted individual, but the reason that the former does not distinguish between rays of light whose difference in wave length is obvious to the latter is because his brain centres are not sufficiently developed to appreciate so small a difference. All, even the best among us, are really very colour-blind, for we are utterly unable to distinguish any difference in colour in large patches of the spectrum; for instance, if a spectrum is looked at and all is cut off except a patch, say, of green, which appears monochromatic, it is impossible for anyone to say which end of this patch corresponds to the red end of the spectrum and which to the violet, while we know there is a considerable difference in the wave-lengths of the rays comprised in this patch. The colour-blind person would in like manner see perhaps the red, orange, yellow, and green all as one colour. Such cases correspond identically with the musician who is able to distinguish small fractions of a tone, while another who has "no ear for music" is incapable of telling and remembering one note from another unless the difference between them is enormous. In regard to the evolution of the colour sense Dr. EDRIDGE-GREEN suggests that to the least developed sense of sight all nature appeared black and white of various shades, as is seen in an ordinary photograph, but as more cells were added to the visual centres rays of low refrangibility were seen as

two colours was visible at each end of the spectrum, with a large neutral band between. These colours gradually approached until they met. The eye then began to be able to distinguish something at the point of juncture where the rays most differed in wave length from the two ends, and these were termed green. Yellow next became interpolated between the red and green, blue between the green and violet, orange between the red and yellow, until some eyes became capable of seeing a distinct colour, indigo, between the blue and violet. As development progresses more colours may perhaps become visible, and what we call normal colour-vision now may not improbably be termed subnormal in years to come. As a retrograde condition we find examples of all the conditions from total colour-blindness to full normal vision existing at the present time. The theory which Dr. EDRIDGE-GREEN develops in his paper proposes to explain the ascertained facts of vision, and much that we know of vision supports it. The Board of Trade, however, will have none of it, preferring to rely upon HOLMGREN'S test. The matter is of vast importance, and it seems to us that the Board of Trade might well refer the questions at issue to an authoritative committee upon which physiologists and ophthalmologists should be duly represented.

Annotations.

"Ne quid nimis."

THE HOUSING AND TOWN PLANNING BILL AND THE HOUSE OF LORDS.

WE do not at the present moment propose to discuss the several mutilations which the House of Lords has inflicted upon the valuable measure of domestic reform which Mr. Burns so ably piloted through the House of Commons, but we feel compelled to protest against the emasculating alterations and deletions which have been made in Part III., which deals with the appointments and duties of county medical officers of health. It was proposed by the Bill that the Local Government Board might, if it thought fit, prescribe the duties of county medical officers of health, and had the clause which provided for this prescription been allowed to remain we might soon have seen a marked quickening in public health administration in rural and small urban districts with a corresponding improvement in the health and conditions of their populations. It is the constant complaint of county medical officers of health that they have so few powers, and had the proposal referred to been accepted by the Lords it is clear that the Local Government Board might have so defined the duties of the officers in question that their spheres of activity would have been greatly enlarged and their inter-relation with district medical officers of health placed upon a better footing. The present position of county medical officers is a very difficult one and the impression left after seeing their work and reading their annual reports is that potentially they are of the highest value, but that it is unusual for their potential energy to be converted into actual energy. Otherwise expressed, they need additional powers and credentials. It is difficult to understand why a body constituted like the House of Lords should have thus shown what appears to be an indisposition to further rural sanitary administration, and the fact of its rejection of this proposal raises suspicions to which party politicians will certainly give voice. We must, too,

express regret that the arrangements made in the Bill by means of which a county medical officer of health could only be removed by his county council with the consent of the Local Government Board have been deleted. Medical officers of health as a whole throughout the country had hoped that in this provision there was the promise of a better state of affairs, of a condition under which they could have performed their work more conscientiously and efficiently without the constant dread that local holders of property who were also creators of nuisance would use every endeavour to terminate their appointments. Perhaps the House of Lords has feared an extension of the principle involved and has decided to nip the movement in the bud. In view of the present temper of the Upper Chamber where the health and social conditions of the people are involved, we must, at any rate for the moment, be content with very small mercies, and in this spirit we give thanks for the fact that the county medical officers, with one notable and conspicuous exception, have been given powers of entry on premises in common with district medical officers of health, but why the inhabitants of the County of London should be debarred from the advantage of this provision is beyond our comprehension. Perhaps we shall hear more of this matter next week, and, if not, we trust that Mr. Burns and the Government will explain to the House of Commons why it is that an advantage, which they intended should apply to England as a whole, has been denied to about a fifth of its population living under conditions which call for inspection at least as urgently as it is called for in rural districts. It would be deplorable were even the semblance of party politics introduced into public health questions by the House of Lords. No greater disaster could befall public health than to become associated with one rather than another political party.

A MEDICAL STOCK-TAKING.

Professor W. Osler may rightly be called the Nestor of British Medicine. Not only does he sit at the fount of medical wisdom in our oldest university, but he has well earned the title by the words of counsel and encouragement to the young practitioner and of sympathy and understanding with the older, which have on many formal occasions fallen from his lips. We have before us a printed copy of one of the latest of his public utterances1 delivered before a body of medical practitioners of Canada. His theme is almost as wide as medicine itself, for he deals with the treatment of disease, a subject which, including, as it necessarily must in ever-increasing measure, the knowledge of preventive medicine, comprises the greater part of our science and the whole of our art. Professor Osler first mentions the two great conceptions of the meaning of disease which were held almost universally from the days of the Grecian fathers until within the memory of men still living—the primitive theological belief that all sickness was the scourge of God for sinners, and the Hippocratic doctrine of the humoral pathology. With these crude conceptions he contrasts the belief of to-day that the ultimate processes of disease, whether arising from within the body or introduced from without, are of a physicochemical nature—a belief which allows of a more rational attempt at their prevention and cure than has ever before been possible. Then follows a jubilant reference to the discoveries of the causes of many of the great scourges, discoveries which have changed the whole outlook of humanity, and a bold assertion of the claim of medicine to have entered an era of progress even greater than that to which

¹ The Treatment of Disease, the Address in Medicine before the Ontario Medical Association, June 3rd, 1909, by William Osler, M.D., F.R.S. London: Henry Frowde. Pp. 26. Price 1s. net.

the Listerian methods have introduced the art of surgery, For the surgical achievements of to-day our admiration is second to none, but too often the cry is raised, and that by well-informed persons, that surgery is leaving medicine far behind. Let them hear what this physician says of modern medicine. "Nothing has been seen like it on this old earth since the destroying angel stayed his hand on the threshingfloor of Araunah the Jebusite." And he makes good his bold saying in words which persons pledged to the antivivisection cause would do well to mark. "For seven years Cuba, once a pest-house of the tropics, has been free from a scourge which left an indelible mark in the history of the Englishman, Spaniard, and American in the New World." Then he contrasts a recent work on tuberculosis with one published 30 years ago, in which the drug treatment, now relegated to a page or two, claimed the largest share of the pages. In such matters as diet, exercise, massage, and hydrotherapy he rejoices that "we are every day finding out the enormous importance of measures which too often have been used with the greatest skill by those outside or on the edge of the profession." We would add that if this formidable type of unqualified practice is to be faced more successfully in the future than has been done by medical men in the past it is absolutely necessary that our students should receive proper instruction in the physical group of therapeutic agents, the importance of which was so well recognised in the temples of Æsculapius. If the knowledge of their application were more widely spread at the present day we should hear less of gymnasium masters professing to cure over 90 per cent. of all diseases which their clients may bring to them for treatment. The discourse passes on to consider a grave problem of what has been aptly termed "pastoral medicine," the question of whether a medical man should tell his patient that he is in a very serious way. Professor Osler says wise words on this subject. We are to regard ourselves as the teachers, not the servants, of those whose bodies are committed to our keeping and on occasion we must sacrifice our own inclinations and tell them what is true rather than what is pleasant. A later part of Professor Osler's address deals with the psychic treatment of disease, about which we have heard so much of late. He does not seek to discount its importance—indeed, he acknowledges a "grain of truth" in a friend's definition of his own practice as "a mixture of hope and nux vomica"—but he would not have the clergy meddle with systematic treatment of the sick in an age which has lost the apostolic gift of healing. His last word concerns the instruction of the student, and it seems to us to sum up the best modern doctrine concerning the place of drugs in the treatment of disease.

THE VALUE OF SYSTEMATIC EXERCISES IN THE TREATMENT OF ORGANIC DISEASES OF THE NERVOUS SYSTEM.

EVER since Dr. Frenkel of Heiden, now about 15 years ago, published his methods of treating the ataxia of tabes dorsalis by physical exercises systematically applied, his ideas have been accepted and their carrying out adopted with the most gratifying results. In every hospital in the world worthy of the name the tabetic finds ready for his use some or other form of apparatus for the prosecution of "Frenkel's exercises." Anyone, however, who cares to read the original paper will note that Dr. Frenkel did not confine the application of his methods to tabes, but specified many other conditions, organic and functional, where they had been of proven value. This has been rather lost sight of, although more attention is now being directed to this side of the subject, and it is therefore interesting to find Professor Karl | cases which formerly occurred in the Japanese navy, there

Petren of Upsala giving out of a wide experience many practical details of the treatment of organic nervous disease other than tabes by Frenkel's methods. In the Archives de Neurologie for August he considers the treatment applicable in two forms: one is compensatory, and is founded on principles of the same nature as those utilised for tabes; the other consists in simple exercises intended to augment the strength of certain groups of muscles. If we take, for instance, multiple peripheral neuritis, physical treatment is directed primarily to increasing the muscular force, and can be attempted only in the stationary or convalescent stage. It frequently happens that some degree of muscular power, insufficient to produce displacement of the limbs, still survives, for patients unable to move their extremities in bed can often do so when in the bath. Sometimes, therefore, it is a good plan to commence exercises when the patient is immersed in water. If he cannot make a given movement unaided, the physician puts the limb into the required position, and as he does so asks the patient's coöperation in attempting it; thus even though the result be minimal the latter has made the effort. If he can execute movements himself, then they are performed regularly at the different articulations several times daily, the physician or attendant offering slight resistance in each case. For each movement exercises must be employed, however paralysed the muscles be. For essaying walking, a go-cart is recommended as the first procedure, but as soon as the patient can stand upright with the aid of his hands Professor Petren advocates the use of what he calls a "passerelle" or footbridge. This consists of a pair of parallel bars, about 12 feet long, the height of which from the floor is that of an ordinary walking-stick. Walking exercises take place in this apparatus, which provides an excellent transition from the go-cart to walking-sticks, and in which, moreover, other exercises than those of walking can be made. The passerelle is greatly to be preferred to crutches; these only serve to perpetuate vicious methods of progression, for the patient never performs movements analogous to those of walking as long as he swings his body on these supports. Many other varieties of organic nervous disease may be treated with considerable success by the application of these principles.

BERI-BERI IN THE TYNE.

ABOUT a fortnight ago, on the arrival of a Brazilian cruiser in the Tyne, it was found that several of the crew were suffering from beri-beri, and they were removed from the ship to the floating hospital of the Tyne Sanitary Authority at Jarrow Slake. The vessel has been under close observation since then, with the result that more cases of the disease were identified, and the subjects, to the number of nearly 20, were also removed to the floating hospital. The cases have not apparently pursued a violent and serious course, but one death has been reported. The cases are understood to have been of the classical clinical types—"dry" and "dropsical," the former variety being the commoner. One other case which was seen first in the Royal Victoria Infirmary was apparently of the "dry" variety, the main symptoms and signs being cough, dyspnœa, pleural effusion, painful limbs, and absent reflexes. regard to the etiology of the disease in these particular cases little can be made out with any definiteness. Inasmuch as the vessel was bringing over a spare crew to man another vessel it is possible that the quarters of the men have been somewhat crowded; of the special character of the food we have no information. Comparing this particular group of cases, occurring in men of the negro type, who are responsible for the roughest class of work at sea, with the appears to be no direct blame attached to the food, for which a strong case was made out in the instance of the Japanese.

A FRENCH VIEW OF THE SWEATING SYSTEM.

THE industrial conditions which have gained an unenviable notoriety under the designation of the sweating system present several features of interest from a medical point of view. Of comparatively recent origin, the term does not seem to admit of any precise definition, but signifies in a general way a system of paying the lowest possible wages for work done by poor people anxious for employment. Wages being subject to economic laws are naturally low when the labour market is overcrowded, but in considering the evils connected with one particular species of illpaid labour it will not be necessary for us to enter into financial details. The rapid extension of the factory system which commenced in England about a hundred years ago laid the foundations of a period of great prosperity in certain trades, especially in the manufacture of all descriptions of cotton and woollen fabrics. At first the bodily welfare of the operatives was not sufficiently regarded. Overwork was universal, parents profited by the labour of their children, and accidents caused by unfenced machinery were incessant. A remedy had to be found for these abuses, but just about the time when legislation and inspection were doing a great deal for the protection of factory operatives new problems of even greater difficulty arose in certain trades employing great numbers of needlewomen, tailors, and shoemakers who worked either by hand or with portable appliances of which a sewing machine driven by foot power was the most elaborate. The essential feature of the factory system is cheap production by the use of expensive machinery which is necessarily the property of the employer, and as the operatives are on the premises only during the hours of their employment inspection is comparatively easy. With the second class of workers the case is quite different, for a large proportion of them, instead of following their occupations on their employer's premises, only call there for the purpose of taking away materials which they convert into finished articles at homethat is to say, in dwelling-houses to which the Factory and Workshop Acts do not apply. An extension of this principle is that the manufacturer may make an arrangement with a sub-contractor or middleman who may either distribute materials to individual home-workers or may have the finished articles made up by persons living and working on premises occupied by him as a dwelling-house. Strictly speaking, the mischief is not confined to the tailoring and shoemaking trades, but for our present purpose a sufficiently accurate definition of the sweating system will be the commercial manufacture of clothing by home-workers in the rooms where they habitually live, and readers of THE LANCET do not need to be reminded that from a medical point of view there are many objections to the practice. Obviously the people who accept such terms belong to the necessitous classes, their habitations are overcrowded and insanitary, and child labour is inevitable. For many years philanthropists have been denouncing this system, and much evidence as to its injurious effects on health has been collected in Europe and America both by medical men and by official commissions of inquiry, the latest of which was the Select Parliamentary Committee on Home Work which sat last year at Westminster. 1 Dr. Lucien-Graux, editor of the Gazette Médicale de Paris, has recently published an important memoir on this subject. He considers that the sweating system, which he designates by its English name in preference to any

French equivalent, originated at Boston in America about the year 1863, and that its subsequent development in that country coincided with the growth of the trade in cheap ready-made clothing. Quoting from the published evidence collected in Chicago, New York, Paris, London, Berlin, and Switzerland, he describes the wretched conditions under which many home-workers live, their overcrowded and illventilated rooms, and the prevalence of tuberculosis and other infectious diseases among them. He draws particular attention to recorded instances of clothing which had become infected in the home-worker's room communicating small-pox and other eruptive fevers to the purchaser, his list of authorities including the report of THE LANCET Sanitary Commission on Sweating and Home-work Systems published by us on Jan. 29th, 1876. In conclusion, Dr. Lucien-Graux discusses at some length the state of the French law with regard to these evils. He thinks that little can be expected from the statutes corresponding to the British Factory and Workshop Acts (la loi sur la réglementation du travail dans l'industrie), but that much good may be done if local authorities will make proper use of the Public Health Acts (la loi sur la protection de la santé publique) and exercise the powers thereby conferred on them for the prevention of infectious disease.

THE EXTRACTION OF VEGETABLE DRUGS WITH GLYCERINE.

PARLIAMENT has decided not to abate any part of the spirit duty proposed in the Finance Bill, and though everyone may not accept Sir William Bull's estimate of the increased strain which the new duties will entail upon hospital exchequers (as reported in our Parliamentary Intelligence on p. 1042), yet these duties will be sufficient to make the substitution of glycerine for alcohol as a solvent of the active principles of vegetable drugs an economical proceeding. This subject is well discussed in a lengthy article by Mr. George M. Beringer on Fluid-glycerates in the current volume of the Proceedings of the American Pharmaceutical Association. The so-called "fluid glycerates" contain 50 per cent. by volume of glycerine and are so adjusted as to strength that one part by volume of the liquid represents the soluble matter of one part by weight of the drug. Glycerine is an indifferent solvent for resins, fats, and fixed oils, and, in fact, for most substances which are perfectly dissolved or extracted by alcohol. On this account it is of but little use as a solvent where such constituents represent the chief active principle of the drug, and its use even in conjunction with alcohol is contra-indicated in such preparations. In the case of drugs which are readily extracted by water the desired substances may be extracted by dilute glycerine, while the oily, resinous, and other undesirable constituents remain in the marc. Glycerine is a good solvent for many of the sweet, bitter, astringent, and essential flavouring constituents of drugs, and exercises a marked solvent action on many of the alkaloids, glucosides, and neutral principles. The fluid glycerate of krameria illustrates the usefulness of this class of preparations. It is made by percolating the coarsely powdered drug with a mixture of glycerine and water, and Mr. Beringer states that clinical experience has demonstrated its value in catarrhal affections of the rectum. In making a fluid glycerate of alkaloidal drugs it is necessary to add a small quantity of acid to the menstruum, while in the case of liquorice and senega it is advisable to add a small quantity of alkali. Mr. Beringer suggests that the fluid glycerates as a class should appeal to physicians as they afford excellent concentrated infusions. Thus the simple dilution of the fluid glycerate with either hot or cold water will supply:a satisfactory substitute for an infusion of such drugs as

aborandi, broom, spigelia, triticum, and uva ursi, all of which are preferably administered in the form of an infusion and yield satisfactory fluid glycerates. Again, alcohol may be contra-indicated, as in cases of hysteria in which it is desired to administer valerian, which yields to glycerine its active constituents. In the treatment of alcoholism it is a great advantage to be able to prescribe the aromatic bitter tonics, such as orange peel, gentian, and chiretta, in a non-alcoholic menstruum, and the fluid glycerates of these drugs have been found satisfactory. Mr. Beringer has given the results of his experiments with nearly 100 drugs. He admits that further work is required to establish the stability of this class of preparations, as well as to determine their chemical and physiological value. In a recent number of the American Journal of Pharmacy Mr. John R. Rippletoe has described his experiments on the physiological action of two of the drugs dealt with by Mr. Beringer-viz., digitalis and ergot. He prepared tinctures and fluid glycerates of these two drugs and compared their physiological activity. The preparations of digitalis were tested on frogs by determining the minimum lethal dose, with the result that the alcoholic preparations were found to be five times more potent than the fluid glycerate. In testing the action of the preparations of ergot equal amounts were injected into the thigh muscle of two roosters. Although the sample of ergot appeared to be of poor quality, a typical darkening of the comb was produced by the alcoholic extract, while the fluid glycerate produced only a slight and transient paling of the comb and wattles. Although these experiments do not afford a perfectly satisfactory method of testing preparations of ergot the results would appear to be in favour of the alcoholic extract. Rippletoe's experiments with these two drugs are not very favourable, but he admits that the fluid glycerates may possess a therapeutic value which can best be proved by clinical tests. It is noteworthy that in many of the fluid glycerates prepared by Mr. Beringer from alkaloidal drugs the finished preparations contained appreciably less alkaloid than did the corresponding alcoholic fluid extracts, which serves to show that the method of preparing the fluid glycerates must be improved before they can be used with assurance in place of the alcoholic fluid extracts. The subject offers a good field for pharmaceutical research.

KISSING THE BOOK.

WE believe that the insanitary possibilities of the usual method of taking the oath in our law courts by "kissing the Book" were first pointed out in THE LANCET in 1885. Certainly from that year onwards we have had frequent occasion to refer to them. It is true that the Oaths Act of 1888 repealed sections of nine older Acts dealing with the methods of swearing witnesses in Great Britain and Ireland, and made it optional for a witness either to take the oath with uplifted hand in the Scotch fashion or to make an affirmation instead of an oath, but in spite of this legislation kissing the Book remained the almost universal custom in the courts, and we have referred to the obvious hygienic objections to its promiscuous public performance over and over again during the last quarter of a century. In these protests we have been supported by many medical men, especially by Mr. F. W. Lowndes of Liverpool, who, since the subject was first broached, has never ceased to speak and write in our columns and elsewhere against the perpetuation of the traditional ritual of the witness-box. It must be a source of gratification to him, as it is to us, that the new Act to amend the law as to oaths has become law upon the first day of the present month. We have reported the progress of the Act

through Parliament, and our readers may remember that it has been under consideration by a standing committee of the House of Commons, which has stated in a memorandum to the Bill that under the Act of 1888 "judges, magistrates, coroners, and other persons do not consider themselves justified in suggesting the form of oath to the witness, jury, or deponent, and it is a question whether the oath ought to be so administered (i.e., in the Scottish fashion) unless the witness or deponent voluntarily requests it to be done. Consequently, the old form of kissing the Book, to which there are many objections, still prevails." The memorandum proceeds to the effect that the object of the new Act is to make the administration of the oath by uplifted hand universal unless the person about to take the oath voluntarily objects to its administration in this form by the court. The words of the effective provisions of the Act are as follows: "Any oath may be administered and taken in the form and manner described in the schedule hereto" and "the officer (i.e., the person duly authorised to administer oaths) shall (unless the person about to take the oath voluntarily objects thereto or is physically incapable of so taking the oath) administer the oath in such form and manner without question." The schedule to which reference is made describes the usual Scotch form of swearing "by Almighty God" with uplifted hand, a form which, in our opinion, is much more solemn and impressive than the perfunctory kissing of a copy of the New Testament, besides being much more ancient. Medical men have frequently to give evidence in the law courts and coroners' courts and we hope that in future they will always elect to take the oath in an unobjectionable form, thereby accustoming the courts to its regular use.

PRESENCE OF THE TYPHOID BACILLUS IN THE MILK OF A WOMAN SUFFERING FROM ENTERIC FEVER.

In the Boston Medical and Surgical Journal of July 29th Dr. C. H. Lawrence has reported a case in which he found the typhoid bacillus in the milk of a woman suffering from enteric fever-an observation which does not appear to have been previously made. The patient was a woman, aged 23 years, who was admitted to the Massachusetts General Hospital on May 13th with the diagnosis of enteric fever. She was nursing a baby of the age of three months. Four days previously she became ill with fever, headache, chilly sensations, and slight abdominal pain. On admission the temperature was 101.8° F., the pulse was 108, and the respirations were 26. Examination of the blood showed that the white corpuscles numbered 4800 per cubic millimetre. The spleen was enlarged. A few râles were heard at the apices of both lungs. The breasts were tense and full of milk, but not reddened or tender. The Widal reaction was negative, but became positive 18 days later. A blood oulture made on a bile medium showed a motile bacillus which was identified as the typhoid. A culture was taken from the milk in the following manner. The breast and nipple were carefully washed with soap and water and boric acid solution. About five cubic centimetres of milk were withdrawn into a clean breast pump and transferred to a tube of sterile ox-bile. This was incubated for 18 hours and a transfer was made to a bloodserum slant medium. After six hours in the incubator an actively motile bacillus was found in the water of condensation. This organism gave the cultural characters of the typhoid bacillus and was agglutinated by the serum of a patient known to be suffering from enteric fever. As the patient's baby showed no signs of illness, the exact significance of the presence of the typhoid bacillus in the milk of a nursing woman remains undetermined. The positive Widal reaction obtained with the serum of infants who have

been nursed by mothers suffering from enteric fever may explain the fact that in the majority of cases the child fails to contract the disease. On the other hand, it is possible that in some cases the reaction is not strong enough to protect the child, and the present case suggests a mode in which nursing infants may contract typhoid fever. We may point out that though Dr. Lawrence's observation appears to be new, the presence of the typhoid bacillus in the blood in enteric fever (probably in all cases) and its presence in another secretion—the urine (in many cases)—favour the conclusion that it should occur in the milk.

MEDICAL ENDOWMENT OF LIBRARIES.

THE National Library of Wales was incorporated by Royal Charter on March 19th, 1907, and a site for the building was given by Lord Rendel consisting of four acres of land close to Aberystwith, which land was handed over to the council of the library by deed of gift in May, 1908. A report dealing with the progress of the library from the granting of the charter up to March 31st, 1909, has been issued, and it is evident that the library is growing both rapidly and wisely. The nucleus of the library consists of certain Welsh printed books and MSS. hitherto kept at the University College. These were transferred to the temporary buildings of the library in February of this year. In addition to this collection the National Library is now in possession of the valuable library which was gathered together by Sir John Williams. and presented by him on Dec. 11th, 1908. Sir John Williams not only formed his collection by the purchase of separate books and MSS., but he was also enabled to enrich it by the purchase of other libraries and collections of MSS. Among the latter are the Hengwrt and Peniarth manuscripts originally in the possession of the Wynnes of Merionethshire. This collection began to be made by Robert Vaughan, 1592-1666, and contains over 500 MSS. in Welsh, Cornish, English, and Latin. Among the Welsh MSS. is the celebrated "Black Book of Carmarthen," which was compiled or composed between 1195 and the thirteenth century in the priory of St. John at Carmarthen. The contents are poems dealing with mythology, religion, history, and literature. Another fine Welsh MS. is one of the history of the Holy Grail. Of the two MSS. in the Cornish language one is unique, being a Cornish mystery written in 1504, and among the English MSS. is one of the Canterbury Tales circa, 1420. Sir John Williams also presented the Shirburn and Parry Llanarmon libraries. Among the treasures of the former is the first book ever printed in Wales, a work on tobacco printed in Trehedyn in 1718. Of books collected by Sir John Williams himself are a valuable set of Welsh Bibles and Prayer-Books, and a series of the works of Henry Vaughan, mystic and medical man. The literature of the Arthurian Romances is also widely represented. It is given to but few medical men to have the means or the leisure for so handsomely endowing the scholarship and "humanities" of their native lands, and Wales may well be proud of her learned and generous son. The report before us does no more than indicate the composition of the library, and we await with interest the publication of the detailed catalogue. Another library which owes its inception to a medical man is the free library of Bethnal Green, which was founded by the late Dr. William Tyler, who sacrificed the ease which a considerable competence would have assured him for a life of unselfish service to the poor. He saw the value of ministering to their minds as well as to their bodies, and his library attracted the notice of the late Queen Victoria as well as of the King and the Prince of Wales, all of whom have contributed to its shelves, which now contain 38,000 books.

We understand from the librarian that his council had to face an adverse balance for several years and is appealing for £10,000 to place the library's work on a sure footing. In support of this appeal it is stated that the institution is not only well used by readers of all creeds, but it is of special importance to skilled workmen in matters of design, and the London County Council school children and their teachers resort to it. Institute work is also carried on at the library, the work embracing free lectures and concerts and evening classes. We are glad to learn that Dr. Tyler's intentions have been so well fulfilled and trust that the desired endowment may be forthcoming.

THE EFFECTS OF RADIUM ON CANCER CELLS.

AT a meeting of the Société Médicale des Hôpitaux of Paris on July 23rd M. H. Dominici and M. Rubens-Duval read an important paper on the Histological Effects of Radium on Cancer Cells. The tumours were exposed to the hard penetrating rays of radium (rayons ultrapénétrants) by the method introduced by M. Dominici of filtering off the softer rays by metal screens which was recently described at the Royal Society of Medicine by M. Louis Wickham. 1 M. Dominici, in collaboration with M. Barcat. has shown that cancer cells which are amenable to radium therapy undergo direct or indirect destruction. Direct destruction consists in necrobiosis of the cells without previous morphological changes. The radium acts as an extraordinarily subtle caustic, producing what M. Gaucher has termed "cellular eschars." Indirect destruction is preceded by the following changes: (1) hypertrophy of the nucleus and body of the cell; (2) budding of the nucleus; and (3) increase in number and size of the so-called "pseudo-parasitic bodies." Glandular cancers, for example, cancer of the breast, undergo these changes, but in cancers originating in the Malpighian layer of the skin an additional change frequently occurs-horny transformations of the protoplasm. Thus a sort of abnormal maturation of the cells occurs. This shows that radium is capable of exercising an influence on the evolution of cells. The following are examples. A woman, aged 77 years, was admitted into hospital in June, 1908, for congestion of the lungs supervening on chronic bronchitis. She also had an ulcerated cancer of the breast. The ulcer was gangrenous and suppurating, and of the extent of 80 square centimetres. The nipple was almost entirely destroyed and scarcely visible at the lower part of the ulcer, where it rested on an indurated mass of growth adherent to the pectoralis major. To the surface of the ulcer was applied an apparatus 6 centimetres in diameter on which were spread 5 centigrammes of pure sulphate of radium, and on this were imposed four pieces of linen, each impregnated with 1 centigramme of pure sulphate of radium. The radiferous apparatus was enclosed in a leaden case 2 millimetres thick, to which were added screens of paper 2 or 3 millimetres in thickness. The whole was enclosed in indiarubber and separated from the tumour by four or five layers of muslin and left in place for 166 hours. Three or four days after the termination of the treatment much serous discharge occurred and was followed by a healthier condition. The gangrene disappeared and the ulcer became of a rosy colour. Six weeks after the application a cicatricial band appeared and spread in a centripetal manner until about half the ulcer was covered. The tissue subjacent to the cicatricial band, which at first was indurated, gradually softened, until in September the tumour was reduced one-half, both in surface and in depth. A further application of radium was proposed, when the patient succumbed to an exacerbation of the pulmonary congestion. At

the necropsy no metastasis of the growth was found. was supposed, the tumour was found to be reduced not only in surface but in depth, and, so to speak, had abandoned the region subjacent to the superficial epidermisation. Its place was taken by normal adipose tissue, excepting small scirrhous bands in which fibrous considerably preponderated over epithelial tissue. Further, the tumour appeared to be separating from the pectoralis major, which it infiltrated only for a depth of 1 or 2 millimetres. The structure of the tumour was found to be profoundly changed by comparison of sections made before treatment and after death. Before treatment the tumour was composed of masses of large cuboid epithelial cells with round nuclei separated by fibrous bands. After death the epithelial growth was so reduced that in areas of from 20 to 30 square millimetres it was represented only by a few widely separated cells. The cells were for the most part hypertrophied and contained an enormous budding nucleus and sometimes enlarged pseudoparasitic bodies. M. Dominici and M. Rubens-Duval also examined three epitheliomata (one of the cervix uteri and two of the lips) treated by radium. The epithelial cells underwent horny transformation, and when this was complete their vitality was lost, and, like foreign bodies, they were destroyed by phagocytosis.

CHINESE PORK.

At the beginning of September several questions were asked of the President of the Local Government Board in the House of Commons as to the wholesomeness of certain batches of pigs' carcasses imported into this country from China for food. Mr. Burns replied that the carcasses were being inspected in the usual manner as they arrived and that the chief medical officer of the Port of London Sanitary Authority was paying special attention to them. He said further that any pork found to be unsound would be condemned in the ordinary course, whatever its port of origin. Dr. Herbert Williams, the medical officer in question, has now presented a report to the Court of Common Council, in the course of which he states:—

the course of which he states:—

On July 24th the s.s. Palermo arrived from China with a general cargo comprising 4663 pig carcasses, pigs' casings and, bladders, chickens, ducks, mallards, plover, bustards, pigeons, geese, snipe, teal, cockerels, and hares. The importation of pigs from China had received considerable publicity in the press, and from questions asked in Parliament, chiefly owing to the apprehension that these pigs might be the wild variety which frequents the streets and public places of Chinese towns, living as scavengers on the food they can pick up in that way. The importer stated that the pigs in question had been bred in the country and fed on rice, and the President of the Local Government Board appears to have confirmed this statement by reference to the British Consul at Hankow. The pig carcasses on arrival were found to be very large and fat, and each one had a label attached to it which indicated that it had been subjected to a medical examination at the port of shipment. It has been stated that Chinese pigs are very prone to contain the parasite which gives rise to the condition known as trichinosis. I therefore selected 100 pigs at random and removed portions of the diaphragm and other muscular tissues, and examined the same microscopically without, however, finding anything which was at all indicative or suspicious of trichinosis.

It is obvious that all proper precautions are being taken in

It is obvious that all proper precautions are being taken in respect of this source of food-supply. No pigs are clean feeders, and probably it was on account of their objectionable habits of "nosing" for food in any filth that their flesh was forbidden to the children of Israel in the oldest sanitary code known to history. But nowadays we have got over the objection to partake of the flesh of any animal which is not a "clean feeder," recognising that in certain instances the alchemy of the living tissues can transform garbage into healthy flesh and blood. Indeed, in the ultimate analysis all our food is built up of molecules derived from decayed and "offensive" matter, re-created by the mysterious processes of the metabolism of the vegetable world into wholesome and necessary foodstuffs. But even though this be the case there is a natural and decent revulsion against the flesh of animals that have fed on excrement, and there is a strong scientific sanction for such a feeling when the of years, and, in fact, an increase in the amount of valuable

animals in question come from a country where a human intestine without its parasite is a rarity. In the case of these Chinese pigs, however, we may reasonably accept the word of the importer, substantiated by Dr. Williams's investigations, that they were reared under conditions of ordinary cleanliness and fed upon wholesome food.

MEDICAL STORIES.

As will be seen by our advertising columns, the editor of the Strand Magazine is offering a prize for the best medical story to be written by a qualified medical man and to be "either fact or fiction." If any of our readers are moved to compete for this prize we suggest they should exercise all discretion in the event of an attempt to employ special personal experience as material for the story. There can be no harm in a medical author drawing upon his general knowledge, but he has certainly no right whatever to repeat in the form of fiction what has found its way into his case-books as fact. We shall be interested to see what the prize story reads like, for stories of medical interest in popular magazines, when written by persons untrammelled by medical knowledge, are invariably mixtures of absurdity and error. Will a medical practitioner, whose invention and imagination must be kept in subjection to his technical knowledge, be able to write a readable story? Whoever does this will be a considerable master of composition, for his suppressions will have to be as artful as his statements. We may add that the author can use a pseudonym.

THE FUTURE OF PHARMACOGNOSY.

THE address delivered by Dr. Tschirch, professor of pharmacognosy and practical chemistry in the University of Berne and the Hanbury medallist for 1909, on the occasion of the reopening of the Pharmaceutical Society's School of Pharmacy on Sept. 29th serves to show what a rich and interesting field of research is offered by pharmacognosy and how many are the problems susceptible of scientific treatment and capable of yielding results of direct practical utility which remain unsolved. While the main purpose of Dr. Tschirch's address was to indicate a few of these problems, it also dealt with the interesting subject of the cultivation of drugs and entered the field of prophecy as to the remedies of the future. We may, said the lecturer, assuredly hope that medicine, when it has thoroughly ruined its digestion with synthetical remedies and tested all the organs of the animal body, will return once more to drugs and will employ them to a greater extent than it does at present. It will return once more to the most ancient remedies of mankind, to the medicinal plants and drugs, for the utility of which the experience of thousands of years vouches. In approaching the subject of the cultivation of drugs, he said that when we had discovered the active constituents, and by the method of analysis made ourselves as thoroughly acquainted as possible with the composition of the drug, we could then proceed to the solution of the problem: "In what way is it possible by suitable cultivation to increase the amount of this or that constituent of a medicinal plant and to diminish the quantity of any other constituent that may appear to be an undesirable admixture?" What he had in his mind was the utilisation of the results of pharmaco-chemical investigations as a basis for physiological researches. experience gained in the cultivation of cinchona trees made the attainment of definite results appear very possible, as, for instance, the production of an opium poor in narcotine, or of a cinchona bark rich in quinine, but containing only small quantities of the other alkaloids. Similar experiments have been made for thousands

constituents has been effected in the case of almost all cultivated plants. He was strongly opposed to the belief that cultivation impaired a medicinal plant and that wild ones are always and without exception the better, and insisted that it was unsuitable cultivation only that produced such bad results. He was convinced that by variation of the conditions of cultivation, by careful selection of suitable strains by crossing, grafting, and other means, brilliant results would be obtained and the object in view ultimately reached. It was easy to understand Tunmann's demand that an experimental garden, in which pharmaco-physiological experiments could be systematically conducted, should be attached to every pharmacognostical institute, for the required knowledge would have to be acquired under such conditions. Proceeding to refer to some of the unsolved problems of pharmacology, he said the fields which were open to pure pharmacognosy and were capable of experimental treatment were very numerous and very varied. In most of them the first sod had only just been turned. In this connexion he alluded to the methods of preparing harvested drugs, especially the so-called fermentation, which must assuredly be systematically investigated, if possible, in one of the tropical laboratories. We are as yet but very imperfectly acquainted with the chemical reactions involved. We do not know either the nature or the extent of the part played by the ferments. At the present time the whole process of the fermentation of tea, cocoa, and vanilla is conducted on a wholly empirical basis, and the result depends more or less on chance, which will remain the case until we have learned how to place this process on a scientific basis and to conduct it rationally. Other problems are to be found in the study of physiological varieties and the substances they produce. We are still, to mention one instance only, ignorant of the reason why the balsam of the Tolu tree, which is scarcely to be distinguished botanically from the balsam of Peru tree, should yield such an entirely different product. These are only a few of the many problems of pharmacognosy which are susceptible of experimental treatment to which Dr. Tschirch alluded.

THE DEVELOPMENT OF PUBLIC HEALTH WORK IN TASMANIA.

THE creation of a public health department for a scattered population of 179,000 persons must have been an arduous task, and the fact that considerable opposition had to be encountered increases our respect for the business capacity of the organiser. The population in question consisted of the inhabitants of the island of Tasmania where the department came into existence on Jan. 6th. 1904, under a Public Health Act which had passed the legislature late in 1903. The Government at the same time appointed Dr. J. S. C. Elkington to be chief health officer in whom the central powers of administration were vested. Up to that time the executive sanitary authority, if such it could be called, had been the Central Board of Health which did not employ either a medical officer or a sanitary inspector. No laboratory existed and the disinfecting apparatus, apart from what had been improvised during a recent epidemic of small-pox at Launceston, comprised a couple of formalin lamps and a small stock of chemicals. The library consisted of one book on sewage disposal and an old set of Tasmanian statutes. The port health inspection of over-sea ships was entrusted to pilots or harbour masters, and the maritime quarantine station was a remarkable example of structural defects. The heavy cost of the small-pox outbreak and the efforts of opponents to sanitary reform rendered Parliament disinclined to incur the further outlay required for effective equipment and maintenance, but it fortunately happened

that the Minister of the day was a medical man and the Tasmanian medical profession gave much support to a system of reform. The population of 179,000 persons was at the time divided up under some 73 local authorities, 28 of which existed in name only, without any officers or organisation, and some had never held a meeting. the remaining 45 local authorities only 16 had officers of health, and 26, whose districts included towns of 500 inhabitants and over, had no system of night-soil disposal. A reorganisation of these local authorities was commenced in 1905, and at present the local sanitary administration outside the two cities (Hobart and Launceston) is vested in 49 municipal councils which possess extensive powers of sanitary rating and administration. 1906 an investigation was made into the physical condition of some 1200 State school children at Hobart by Mr. A. H. Clarke and Dr. Elkington, and in the ensuing year a. system of medical inspection of schools for Tasmania was. introduced, but food inspection, being left by the Act entirely to local authorities, is practically a dead letter. The cost of central sanitary administration has averaged a little more than 2½d. per head of population per year. In conclusion, Dr. Elkington says that the work of his department has received the generous and hearty support of the Government whenever financial exigencies have permitted it; he also believes that the great majority of local authorities now admit that the requirements of the department are reasonable. The equipment at the disposal of the central authority now consists of a fairly well fitted-up bacteriological laboratory, a reference library of several hundred volumes, a portable steam disinfector, and apparatus for disinfection on a larger scale. A sanitary inspector has also been appointed and all over-sea vessels are visited by medical officers before receiving pratique. It is evident that public health questions have become better understood in Tasmania during the last six years.

ADRENALIN AS AN EMERGENCY TREATMENT IN CERTAIN FORMS OF NON-CORROSIVE POISONING.

WE have received a reprint of a paper published in the Intercolonial Medical Journal of Australasia of July 20th by Mr. Judah L. Jona recording some observations on the use of adrenalin as a means of delaying the absorption of certain rapidly acting poisons, and thus giving longer time for the effective use of the recognised antidotes. The antidote for poisoning by cyanide generally recommended is that advocated by Professor C. J. Martin and Mr. R. A. O'Brien, which consists of 30 cubic centimetres (1 ounce) of a 23 per cent. solution of ferrous sulphate, 30 cubic centimetres of 5 per cent. solution of caustic potash, and 2 grammes (30 grains) of magnesia. The first two solutions should be kept in hermetically sealed phials. It is recommended that the three substances should be mixed when required and immediately taken. The principle of the method is the formation of Prussian blue, which is practically innocuous. In observations on rabbits Professor Martin and Mr. O'Brien found that using a lethal dose death invariably occurred unless the antidote were administered within five minutes of the poison. Mr. Jona rightly points out that in a rapidly acting poison like cyanide of potassium, even in very favourable circumstances, more time than this may elapse before the antidote can be prepared and given. Exner has shown that intraperitoneal injections of adrenalin diminish the rate of absorption of strychnine introduced into the stomach, and Mr. Jona therefore decided to try whether adrenalingiven by the mouth would exert a similar effect. He first demonstrated that adrenalin could exert its vaso-constrictor action after the arteriolar wall has been subjected to the action of cyanide of

potassium, and then studied its effects upon rabbits poisoned by the cyanide. He was able to bring about recovery after longer periods than in rabbits which had not received adrenalin. He recommends the following procedure for cases of cyanide poisoning in man. Adrenalin should be given immediately, 9 cubic centimetres (i.e., 3 drachms) of the 1 in 1000 solution diluted to 90 cubic centimetres being used; then Professor Martin and Mr. O'Brien's antidote if available. The stomach should then be washed out and a further dose of about 5 cubic centimetres (1½ drachms) of 1 in 1000 adrenalin solution diluted to 50 cubic centimetres should be given. A brisk saline purge is also recommended to be administered soon afterwards. Professor Martin and Mr. O'Brien found in their experiments on rabbits that if death did not take place within 30 minutes of administering the cyanide recovery occurred. Some experiments made with strychnine followed by adrenalin gave similar results, the adrenalin obviously retarding the absorption of the strychnine, and enabling the animals to be treated with greater success. These experiments, which were carried out in the Physiological Laboratory of the University of Melbourne under the direction of Professor W. A. Osborne, have an obvious practical application, and, as Mr. Jona points out, there is no reason why adrenalin should not be as efficacious in the case of other non-corrosive poisons. In the treatment of rapidly acting poisons it promises to be an adjunct to the ordinary treatment of considerable value, and it should certainly find a place in the list of antidotes, and should be kept handy by all medical practitioners who have to treat emergency cases. We are glad to give further publicity to a well-conceived and useful piece of work.

WASSERMANN'S REACTION IN CHILDREN WITH HEREDITARY SYPHILIS.

An interesting paper recording some observations on Wassermann's reaction in the children of syphilitic parents is contributed by Dr. W. Knopfelmacher and Dr. H. Lehndorff of Vienna to the Wiener Medizinische Wochenschrift of Sept. 18th. It has been already established that in an infant with a recent rash Wassermann's reaction gives a positive result almost without exception. Children born of a syphilitic mother and subsequently developing syphilitic symptoms often give a negative reaction at birth but develop a positive one at the time of the appearance of the exanthem. The recent observations were made upon 33 children with hereditary syphilis and 11 apparently healthy ones whose mothers were syphilitic or whose older brothers and sisters had come under observation and treatment. writers summarise their conclusions as follows. Children with hereditary syphilis give almost invariably a positive Wassermann's reaction at the time of the rash and often many months after its disappearance. Older children with hereditary syphilis show a positive reaction even more frequently than adults with acquired syphilis in a late stage, and the reaction often remains positive in children suffering from the disease in spite of energetic treatment. That antisyphilitic treatment of the mother during pregnancy can result in the birth of a healthy child is confirmed by the negative result of the reaction in such children. Syphilitic women with a positive reaction can bear children with permanently negative reaction. These children are free from syphilis, and they may be quite healthy or show various defects. In two instances a woman who has previously had several syphilitic children has borne children are to be regarded as latent syphilitics. On this basis Profeta's law (immunity of the healthy children of a child which has remained healthy in the first years of life

syphilitic mothers) finds its explanation on the ground of latent syphilis in the child.

THE Conjoint Examination Board of the Royal Colleges of Physicians of London and Surgeons of England has acquired a site for the erection of the new Examination Hall in Queen's square, and the plans for the erection of the building are now under consideration. The building will not be completed for at least two years, and in the meantime arrangements have been made by the Royal Colleges to continue in the occupation of offices and examination rooms at the Examination Hall on the Victoria Embankment, the entrance to which is on the west side of the building, facing the Savoy Hotel.

THE King has been pleased to appoint Mr. Thomas Hastie Bryce, M.A., M.D., to be Regius Professor of Anatomy in the University of Glasgow, and Mr. John Marnoch, M.A., M.B., C.M., to be Professor of Surgery in the University of Aberdeen, both appointments bearing date Sept. 18th.

THE annual medical service of the Guild of St. Luke at St. Paul's Cathedral will be held on Wednesday, Oct. 20th, at 7.30 P.M., when the preacher will be the Rev. Fr. Waggett, S.S.J.E. Further particulars can be obtained from Mr. C. St. Aubyn-Farrer, 1, Harley-street, W.

PLAGUE is increasing in Mauritius. A telegram received from the Governor by the Secretary of State for the Colonies stated that 15 cases of plague with 10 deaths were reported during the week ending Sept. 23rd.

THE HOUSING AND CONTROL OF NAVVIES.

ONE of the most noticeable features of the development of public health administration is the manifold subjects with which it concerns itself, and at the present time it appears to be steadily and surely extending its operations in such a fashion as to embrace social and philanthropic questions which even one decade earlier would have been regarded as exclusively the function of the clergyman or social reformer. But no one conversant with the condition of the poorer classes can doubt that in the improvement of their general social condition we have a more potent weapon for good than in the limited operation of the Public Health Acts, and history, of course, teaches that it was the work of social reformers, such as Lord Shaftesbury, which led to the passing of many of the statutes which now govern public health administration. It is interesting to see the Central Health Department devoting, through its medical inspectors, much time and thought to the social conditions of the navvy who has not many friends and who is in large part outside the scope of the general operations of the Public Health Acts. 1

The public as a whole are not perhaps fully aware of their obligations to that somewhat nomadic tribe which we speak of as navvies, although it is to them that we owe in large part the actual construction of our railways, our waterworks, our tunnels, and a host of other public works with which there is associated in the public mind merely the name of the engineer or the contractor. who performed the rough and manual labour in circumstances far from satisfactory are given but scanty attention. As Dr. Reginald Farrar tells us in his recent report to the Local Government Board, "navvies move about from one public work to another, a distinct class or tribe separated by habit or circumstances from the rest of the community," and it is estimated that in this country navvies and their families

amount to about 100,000 persons. It is, of course, possible that what may be termed the public health side of this class is not of paramount importance, although in times of small-pox prevalence they may undoubtedly by their habits and ignorance play a by no means negligible part in the spread of that disease. A perusal of the report before us suffices to show that the main problem connected with the navvy is a social rather than a public health one. the early days of railway construction there was frequently no housing accommodation for these men; "many slept in sod huts which they constructed for themselves; wages, about half-a-crown a day, were paid at fortnightly, or in some cases monthly, intervals, and most contractors kept provision stores and paid men partly in food tickets, sometimes even forcing them to take a percentage of their pay in beer." As has been the case in so many instances in other public health problems, a Select Committee of the House of Commons took evidence and reported as far back as July, 1846, that the navvies were crowded into unwholesome dwellings with little provision either for their comfort or decency of living; they were exposed to great risk of life and limb, and there were inducements to the men to become thoughtless, thriftless, and improvident, while the committee could not wonder at the "feelings of dislike and dismay with which the permanent inhabitants of a neighbour-hood often view the arrival of these strangers amongst But there the legislature appears to have left the them. matter, and the improvement which has subsequently taken place has, Dr. Farrar tells us, been due to the growth of philanthropy, pressure of public opinion, and the influence of such bodies as the Navvy Mission Society. Nevertheless the report of the committee is still to some extent applicable to existing conditions, and Dr. Farrar shows that there is still a very great deal to be done before the public health authorities can rest satisfied that elementary justice has been done either to the navvies or the public.

There is apparently some sort of combination amongst the navvies themselves, and a deputation from the Mission Society recently waited upon Mr. Burns to protest against the employment of local unemployed to the exclusion of regular navvies, a position which presents considerable difficulty for local authorities who undertake works for the special relief of local out-of-works. It is in the main the navvies employed in connexion with the relatively smaller undertakings who need protection, because it is on these works that the amount of profit may be small and the contractor may be indisposed to make provision for the comfort of the men. But need for regulations is in no sense confined to the smaller works, and we are told that there are at present many works on which scores or hundreds of genuine navvies are "sleeping rough" night after night. When pipe tracks are being laid the men have slept night after night in the pipes themselves, and it is thought that some hundreds of navvies regularly seek sleep in hay-stacks, straw-yards, and cowsheds, or even in hen-houses and pigstyes, and, as Dr. Farrar says, "life under these conditions is conducive to physical ill-health and moral deterioration.

But through all these difficulties there are unmistakeable signs that what may be termed the natural law of supply and demand is in itself bringing about a better state of affairs, much in the same fashion as is the case with the housing problem in the country as a whole. We are told that a contractor who provides proper lodging for his workmen can attract and retain a sufficient number of competent men, and that the services of strong, steady, and respectable navvies are greatly in demand. On the other hand, a contractor who makes no proper provision has to put up with men of an inferior stamp, who are content to "sleep rough" in the fashion above referred to. It is instructive, and in a sense consoling, to hear that when public funds are being spent, as was, for instance, the case in works constructed by the Derwent Valley Water Board, where there was no question of private profit for the undertaker, and no temptation to save money at the expense of the labourers' comfort, the conditions were satisfactory.

Dr. Farrar calls attention to many reforms which are not only of public health import but which relate to problems of Poor law and unemployment, and he points, amongst other things, to the need for discrimination in the casual ward between the loafer and the genuine work-seeker in order that the latter may be liberated sufficiently early in the day to | probably effect a saving of over £6000 a year.

enable him to pursue his quest with more hope of success than if he is retained to perform the usual task. criticises adversely what is known in navvy parlance as "subbing"—that is to say, the practice of paying daily instalments of wages in place of the whole wage weekly or fortnightly. The daily "sub" is conducive both to thriftlessness and inebriety and tends to deprive the family of its proper weekly allowance. The need for a labour exchange and for cheap railway fares are amongst the other points dealt with in the report, which concludes with the following series of very reasonable recommendations:—

1. That every corporate body or contractor intending to commence works of public construction involving the employment of navvies in any district, on which any number of workmen exceeding 100 not previously resident within three miles of the works shall be employed, should be obliged to notify the Local Government Board, and also the county council, or the sanitary authority of the district, as may be hereafter determined, of such intention, not less than 14 days before the commencement of such works, indicating the general scope and the probable duration of such work, and approximately the number of workmen it is intended to employ. If at any date subsequent to the commencement of the work a larger number of workmen shall be employed than were specified in the original notification, a further notification specifying approximately the number of such workmen should be made as above. On the completion of such works the central and local authorities should again be notified.

2. That such works should from time to time be open to inspection

2. That such works should from time to time be open to inspection by inspectors of the Local Government Board.

3. That contractors should endeavour to arrange with the railway companies for the granting of specially cheap fares to workmen.

4. That workmen should, if necessary, receive instalments of their wages during the first fortnight of their employment, but that after this time wages should be paid weekly, and that no contractor should advertise "Sub Daily," or words to that effect, as an inducement to attract labourers to any work.

advertise "Sub Daily," or words to that effect, as an inducement to attract labourers to any work.

5. That any contractor or employer of labour on works of public construction who shall employ on such works any number of workmen exceeding 100 not previously resident within three miles of the works should, except as hereinafter provided, and unless sufficient and satisfactory accommodation already exists in the neighbourhood, be obliged to provide accommodation for such workmen to the reasonable satisfaction of the county council or the district council as may be hereafter determined. The temporary buildings to be provided should, unless the duration of the work is likely to be very short, include buildings sufficient for the isolation of cases of infectious disease that may occur among the workmen or their families. Temporary buildings provided for the accommodation of workmen should be registered by the county council or the district council, and should be open to inspection by persons duly authorised by either of these bodies. If, however, temporary buildings be erected within three miles of any part of the works, for the accommodation of workmen employed on such works, by private persons other than the contractor or employed to such works, by private persons other than the contractor or employed to council, be accepted in lieu of provision made directly by the contractor or employer, but should be subject to the same conditions as to the character of the accommodation provided, registration, and inspection as if they were provided by the contractor or employer. or employer.

6. The medical officer of health for the district should, when such o. The medical officer of neath for the district should, when such temporary buildings are first erected, and afterwards from time to time, examine and report to his council whether in respect of construction, lighting and ventilation, water-supply, drainage, and excrement and refuse disposal those buildings are of a satisfactory character, and whether the cubic accommodation of the sleeping apartments is such as to afford not less than 300 cubic feet of free airspace for each occupant.

7. The provision of the necessary temporary buildings should, unless the duration of the work is likely to be very short, be held to include the provision of a suitable room for purposes of recreation.

8. Temporary shods in which meals can be taken and food warmed should be provided on all works.

9. On all works on which more than, say, 200 men are employed a canteen should be provided in which light refreshments and non-intoxicating liquors may be sold. If intoxicating liquors are sold in such canteen the manager should receive no profit on and have no interest in the sale of such liquors.

10. No intoxicating liquors should be allowed to be sold in any temporary building other than the authorised canteen.

11. A clause requiring the provision of accommodation on the lines above laid down should as far as practicable form part of all contracts and all Acts of Parliament authorising public works of construction.

NEW INFIRMARY FOR THE CITY OF LONDON.new workhouse infirmary was opened by the guardians of the City of London on Sept. 25th. The building, which is situated at Homerton and will replace the Bow Infirmary, will accommodate 681 inmates and 63 officers and has cost nearly £60,000; it includes a block for lunatics. The Rev. T. Greear, chairman of the board, who unlocked the door of the building with a gold key, and afterwards unveiled a commemorative tablet, made a speech in which he pointed out that the increase of commercial life in the City had resulted in a great diminution in the number of people for whom Poor-law provision must be made, and that the present amalgamation of Homerton and Bow workhouses would

REPORT OF THE MEDICAL INSPECTOR OF PRISONS FOR THE YEAR 1908-09.

In his report to the Commissioners of Prisons for the year ending March 31st, 1909, the medical inspector, Dr. Herbert Smalley, is able to give a very satisfactory account of the sanitary condition of the prisons and of the health of the inmates.

During the year 205,681 prisoners were received into the local prisons, being an increase of 9448, as compared with the previous year; and the daily average number under detention amounted to 18,923, the figure for 1907-08 being 17,719. The total number of deaths during the 12 months was 123-99 of males and 24 of females. Of this number 91 were due to natural causes, which, in terms of the number of prisoners received, gives a death-rate of 0.41 per 1000, the average for the preceding 25 years being 0.54 per 1000. It is interesting to note in connexion with the lurid statements which have recently been made regarding the health of prisoners in Holloway that the deaths at that prison from natural causes during the year amounted to four, being thus at the rate of 0.32 per 1000 of the prisoners admitted to that institution. Of the deaths from non-natural causes, 16 were due to judicial hanging, 14 to suicide, one to accident, and one to the effects of poison taken prior to the prisoner's reception into gaol. The number of suicides is somewhat higher than it has been for the last few years.

Twenty-seven cases of infectious disease were notified during the year, comprising 14 cases of erysipelas, five of enteric fever, three of diphtheria, two of measles, two of scarlet fever, and one of puerperal fever. All the cases were sporadio, and in most of them the infection was clearly contented before reconting into micro. The The number of tracted before reception into prison. prisoners released on medical grounds during the year was 111—32 males and 79 females. As usual, the chief reason for release was advanced pregnancy (70 cases); in most of the other cases the prisoners were suffering from diseases requiring surgical intervention. 135 prisoners—97 males and 38 females—were certified insane in the local prisons, the average for the last ten years being 133.4. In considerably more than half the cases the prisoners showed indications of insanity when received into prison. There were also 323 cases of insanity of remanded and other unconvicted prisoners (226 males and 97 females) dealt with during the year, including 24 males and 10 females found "insane on arraignment," and 161 males and 77 females found insane on remand from police or petty sessional courts. If details could be given in the tables concerning these cases as is done with regard to insanity in convicted prisoners, the information would probably be of much interest both from the medico legal and from the psychological point of view. 259 prisoners were reported as being so feeble-minded as to be unfit for the usual penal discipline, this number being a good deal less than for the past two or three years. The cause of this decrease does not appear to be very plain, but Dr. Smalley suggests that one reason may be that magistrates are more alive to the significance of minor degrees of mental defect as qualifying criminal responsibility, and are, therefore, less disposed to commit feeble-minded persons

to gaol.

In the convict prisons during the year the daily average number under detention was 3106—2975 males and deaths from natural causes, giving a death-rate from such causes of 5.9 per 1000 of the daily average population, as compared with 6.5 in the preceding year. Three deaths were ascribed to pulmonary tuberculosis, the mortality from that disease being thus a shade under 1 per 1000 of the daily average number of prisoners. 23 convicts, all of them males, were certified insane.

The large amount of attention and criticism which has recently been given to the existing methods of dealing with the various categories of socially unassimilable persons has led Dr. Smalley to devote part of his report this year to a very interesting survey of the effects upon the medical administration of prisons which would probably follow from the adoption of all the important proposals which have been a very interesting survey of the effects upon the medical administration of prisons which would probably follow from the adoption of all the important proposals which have been put forward by the Royal Commission on the Feeble-minded, the Poor-law Commission, and the Departmental Committees on Vagrancy and on Inebriety. These several inquiries have all a rate was 13.4 per 1000, to County Clare, where it was 14.4

confirmed the opinions expressed by the prison authorities, and with special force and clearness by Dr. Smalley himself, as to the large proportion of persons of weak intellect amongst the petty offenders, tramps, and habitual drunkards who form so considerable an element in the prison population. If the suggested reforms are carried into effect, and if these feeble-minded persons are segregated in special institutions under medical control, it is estimated that the alteration would remove from the prisons at least 3 per cent. of their present inmates, and possibly a proportion even three or four times greater. And, of course, if the specific proposals regarding inebriety and vagrancy are adopted in such shape as to enable other and more appropriate methods than imprisonment to be applied to tramps and drunkards who are not weakminded, the result on the prison population will be enormous —how enormous we may readily imagine when we remember that one fifth of the males committed to gaol are sent for begging, sleeping out, or Poor-law offences, while over half the women prisoners and nearly a third of the men are convicted for drunkenness. The advantages from the point of view of prison administration of elearing out from the prisons the drunkard, the tramp, and the imbecile would be obviously very great; such a change, as Dr. Smalley points out with reason, by allowing prisons to be used exclusively for the treatment of the criminal, would greatly facilitate the extension of those methods of individualisation in treatment, of the value of which the success of the Borstal system is already giving proof.

ANNUAL REPORT FOR 1908 OF THE REGISTRAR-GENERAL FOR IRELAND.

WE have received the forty-fifth detailed annual report of the Registrar-General for Ireland, a document which is full of interesting information respecting the causes of mortality and its incidence on various localities and on sections of the population. This report was presented to the Lord Lieutenant on July 5th last. The members of our profession in the sister isle will therefore doubtless be grateful to Sir Robert Matheson for the promptitude with which he has placed at their disposal information that must prove helpful to practitioners generally, whilst to those who are locally responsible for the state of the public health it is obviously indispensable. Sir Robert Matheson attributes the early appearance of his report in great measure to the exertions of his medical colleague, Dr. Ninian M. Falkiner, who has personally analysed the causes of death and completed the tables at the earliest possible moment, thereby greatly enhancing the value of the vital statistics for purposes of public health. We hope that the authorities at Somerset House will follow the example of their Irish colleagues, so that the reports of the English Registrar-General may in future be issued in time to be really serviceable for administrative purposes.

In recent years the population of Ireland appears to have been almost stationary; but inasmuch as the "natural increase" of the population, by excess of births over deaths, was greater last year than the loss by emigration, the Registrar-General estimates that, as compared with the previous year, there was an increase of 1853 in the numbers living in Ireland. The rates of marriage and of birth were slightly above the decennial averages, whilst the death-rate was below the average by 0.2 per 1000 living. As in previous years, the present report contains instructive particulars of mortality in the different social grades of the people. Among the families of the professional and independent class the mortality last year was equal to a rate of 14.4 per 1000 living in that class; among the middle class it was 15.9; among artisans and petty shopkeepers it was 17.6; whilst among the general service class it was 22.8 per 1000. We trust that at the forthcoming census steps will be taken to provide for the calculation of similar social statistics for England and for Scotland likewise.

per 1000. Of the total deaths registered in Ireland, 14.7 per cent. occurred in workhouses, and 4.3 per cent. in infirmaries or ho pitals. In the section dealing with the causes of mortality it is stated that 25 per cent. of the total deaths in Ireland were returned as uncertified, either by medical men or by coroners, as against 1.45 per cent. in England and 2.3 per cent. in Scotland. In Dublin, Belfast, and most of the other urban centres death certification appears to be satisfactorily carried out; the bulk of the uncertified deaths are recorded in the sparsely peopled rural districts, where the difficulties of obtaining medical assistance are exceptionally great. Sir Robert Matheson explains that the high proportion of uncertified deaths is due to the circumstance that in Ireland many of the poorer classes refrain from seeking medical advice for the very old and for the very young, as well as for those who are afflicted with chronic diseases.

In Ireland the method of classification of causes of death is the same as in England and in Scotland, being based on the nomenclature of diseases issued by the Royal College of Physicians of London. Among "General diseases" typhus fever, influenza, measles, whooping cough, and diarrhoad affections showed increased fatality last year, as compared with its predecessor; whilst scarlet fever, enteric fever, and cerebro-spinal fever were less fatal. Perhaps the most interesting section in the report is that which relates to the behaviour of typhus fever in Ireland; it shows how completely this pestilence is amenable to control by hygienic methods. Special reference is made to a table showing the deaths from typhus fever in each of the 39 years down to 1907. From this it appears that in the year 1880 not fewer than 891 deaths from typhus fever occurred in Ireland, whilst last year the number did not exceed 59. "There is no doubt," says the Registrar-General, "that this reduction is principally due to the measures that are generally so promptly taken to diminish the spread of infection." The reduced mortality from enteric fever is another gratifying feature in Irish statistics, the number of deaths referred to this disease last year having been the lowest hitherto recorded. In the course of the last 11 years there has been a reduction of enteric fever mortality equal to 75 per cent. The local distribution of the disease is set forth in the report; and, as is the case in England, the fatality is highest in the large town districts, and lowest in the rural areas.

The Registrar-General reports a decline in the mortality from tuberculous disease of all kinds in the year 1908. Compared with the previous year there were 386 fewer victims to its ravages, and a corresponding fall is observable in the fatality of the pulmonary variety of this disease. The campaign against tuberculosis is being carried on with great success by the Women's National Health Society of Ireland. which was recently inaugurated by Her Excellency the Countess of Aberdeen. In the words of the report: "The tuberculosis exhibitions held under the auspices of Her Excellency in all the large towns, and the tuberculosis vans which, under her direction, have travelled through many of the rural districts have instructed the people as to the infectious nature of the disease and the means of protecting themselves from its ravages; and evidences are not wanting that the lessons thus inculcated are bearing fruit, and that in many places there has been a material change for the better amongst our people in their habits and surroundings.' We believe that in Ireland the registrars are for the most part medical practitioners, consequently their reports on the sanitary condition of their districts are exceptionally valuable for administrative purposes. For example, one of the registrars reports with reference to the work of the National Health Society: "There is a great improvement with regard to cleanliness in dwellings. People are beginning not to be frightened of fresh air." Another registrar writes that: "The people seem to be awakening to the fact that the inroads of tuberculosis may be lessened by the timely adoption of suitable means." Yet another registrar reports that the sanitary state of his district is greatly improved and that the houses are now being kept clean and well ventilated. By means of a diagram the mortality from tuberculosis in Ireland is compared with that in England, and also with that in Scotland, in each of the 45 years from 1864 to 1908. The diagram shows that between the first and last years of this period the English rate declined from 3.3 to 1.6 per 1000,

but that the Irish rate, instead of falling, has actually risen by 0.2 per 1000 in the same interval. In this connexion, however, regard must be had to the fact already alluded to, that only three-fourths of the deaths from all causes are medically attested in Ireland. In another useful and interesting diagram, which appears in this report for the first time, the fatality of tuberculosis at ages above 15 years is exhibited in relation to the conjugal condition of the people. From this we learn that the average tuberculous death-rate of the unmarried is 3.54 per 1000 for males and 3.26 for females. In the case of the married the rate for hasbands is 2.07 per 1000 and that for wives is 2.70 per 1000. Again, the diagram shows that in Ireland generally tuberculosis exacts a much heavier death-toll among widowers than among widows. We further note the insertion of an interesting table indicating the fatality of tuberculous disease among the various social grades inhabiting the Dublin registration area. From this it appears that whilst in the families of the professional class it is responsible for a mortality at the rate of 73 per 100,000 living, it ranges upward through rates of 223 in the middle class and 371 in the artizan class to a rate of 399 per 100,000, or more than five times the first rate, in the general service class.

Malignant disease does not appear to claim an increasing proportion of victims in Ireland at the present time. In the year 1906 the rate of mortality referred to this cause was 793 per 1.000,000 living and was the highest on record. In the following year the rate fell to 762 per 1,000,000 and to 758 per 1,000,000 in the year under present notice. In addition to the deaths specifically referred to malignant disease, there occurred last year 52 deaths ascribed to "tumour" simply. Apparently the Registrar-General makes inquiry respecting the true nature of the deaths thus indefinitely returned; but in the absence of necropsies it is of course possible that some of the tumours may have been cancerous in their nature. "The preservation of infant life," says Sir Robert Matheson, "is one of the principal objects in the work of sanitary reform." In the year under notice the death-rate of infants in Ireland averaged 97 per 1000 births, which was below the English rate by 24 per 1000, and below the Scottish rate by 13 per 1000. In the "civic unions" of Ireland the rate averaged 130 per 1000, and in the remainder of that country it was 75 per 1000. A table similar to that prescribed by the English Local Government Board is included in this report showing the causes of infant mortality at several stages of the first year of life. As is the case in England, the mortality of infants in Ireland is mainly due to diarrhoeal diseases, convulsions, wasting diseases, and affections of the respiratory system. Towards the close of his report the Registrar-General expresses regret that so large a number of deaths are still referred to ill-defined or not specified causes, a fact which affects the interests of the public as well as those of the medical profession. He therefore again appeals to the medical profession in Ireland to help him in presenting the vital statistics of the country in the most perfect manner possible, and to avoid the issue of medical certificates containing ill-defined causes of death.

LECTURES ON SCIENTIFIC MICROSCOPY.—From Oct. 11th to 16th a series of lectures and practical demonstrations in microscopy will be held at the Institute for Microscopy of the University of Jena. The lecturers are Professor H. Ambronn, Dr. H. Siedentopf, and Dr. A. Köhler, the subjects dealt with being: Abbe's theory of the formation of the microscopic image; the use of Abbe's diffraction apparatus; the method of testing objective glasses; the Abbe test plate and the Abbe apertometer; dark ground illumination; photo-micrography; the use of ultra-violet light; and the ultra-microscope. The demonultra-violet light; and the ultra-microscope. The demonstrations include the investigation of colloids. Application for admission to the course should be sent to Dr. Ehlers, Jena, Beethovenstr. No. 14. Only a limited number of applications can be accepted for the practical lessons and demonstrations, and it is requested that early entry should be made. The subscription for the lectures, demonstrations, and practical lessons, which will cover a period of 18 hours, is 20s; and for the lectures only (nine hours), 6s. The microscopes and apparatus will be lent by Messrs. Carl Zeiss. next series of lectures will be held from March 7th to 12th, and that the Scottish rate declined from 3 ·6 to 2 ·1 per 1000; | 1910, in the Anatomical Institute of the University of Leipsic.

THE BORSTAL SYSTEM FOR THE TREATMENT OF JUVENILE-ADULT CRIMINALS.

II.1

THE experiment of treating adolescent offenders on the lines indicated in the preceding article was commenced a few years ago when part of the disused convict prison at Borstal, near Rochester, was opened as a reformatory for the reception of juvenile-adult prisoners from the metropolitan area; and it is on this site that the new reformatory, which will be the prototype of the Borstal institutions throughout the country, is now in course of erection. The new structure, which is being built in large part by the labour of the young prisoners, for whom this work is, of course, a very useful form of technical training, is already in a sufficiently advanced state to give a fairly good impression of what it will be when completed; and as it represents in many respects the latest developments in prison engineering, some account of its chief characteristics may be of interest.

The cellular part of the reformatory consists of four pavilions, lying two on either side of a central block which comprises the administrative offices and the various communal buildings-viz., the chapel, gymnasium, kitchen, and hospital. The cells in each pavilion are arranged on either side of a central corridor and are in two tiers, the cells in the upper tier opening on to a light gallery. In their general character the cells conform to the type which has been evolved in the modern English prison. Each one has a cubic capacity of 622 feet and is supplied with fresh air through a hit and miss ventilator which is placed behind the hot-water pipes near the floor, so that the air is warmed in entering. There is also direct access of air under the prisoner's control through a sliding pane in the window. The foul air is passed into the corridor through gratings placed over the door. Each cell has a large window of clear glass measuring 2 feet 6 inches by 3 feet 9 inches, and artificial light is provided by means of an inverted incandescent gasburner fixed above the immoveable table. The corridor is thoroughly ventilated by opening sashes at the clerestory level above the upper tier of cells, as well as by large windows at either end. A series of cowled extractors along the crest of the roof provide exit for foul air. The number of cells in each pavilion is 100, so that the whole reformatory when completed will provide accommodation for 400 prisoners, which is probably as many as can be treated in a single institution of the kind with due regard to individualisation of care.

Daily routine.—The Borstal day begins at 5.30 A.M., when the prisoners rise, wash and dress, and clean their cells. From 6.10 A.M. to 7 A.M. there is physical drill, carried out in general accordance with the syllabus of physical exercises recommended by the Board of Education for use in public elementary schools. Drill is followed by breakfast, after which the prisoners go to work in the various shops till dinner at mid-day. A further spell of labour lasting three and a half hours and an hour of school instruction occupy the afternoon. At 5.30 P.M. supper is served out, and after supper there are prayers in chapel. An hour's leisure is then allowed in the cells, or in the case of the better-conducted lads in associated recreation, before the prisoners are locked away for the night. This routine is modified on Saturday afternoons when the boys are associated for half-an-hour's singing practice and have their weekly bath. Sunday is mainly devoted to religious instruction and to reading in cell.

Diet.—As due attention to the physical development of the juvenile-adult prisoners is a specially prominent feature in the Borstal system, the question of food is of capital The dietary scale at present in force is a slightly modified form of the C Diet of Local Prisons, the proportions of fat and proteid being somewhat higher in the Borstal menu. Breakfast consists of 8 ounces of wholemeal bread with 2 ounces of margarine and a pint of porridge (made with 3 ounces of coarse Scotch oatmeal). The rations for supper include the same amount of bread with a pint of cocoa, and on three days in the week 2 ounces of cheese.
At dinner 8 ounces of bread and 12 ounces of potatoes are

of its working may suggest some alterations in its details.

Physical exercises.—Pending the opening of the gymnasium, which is now practically completed, the physical training being given at Borstal consists in daily drill in the open air. Special stress is laid on the movements which tend to develop the respiratory function and on those that have an educative influence on the power of attention and inhibitory control. This is a part of the discipline which is highly appreciated by the boys, and it is found to have excellent results, physical and moral. A feature of the Borstal system, which is quite a new departure in reformatory treatment in this country, and one which will be welcomed by those who recognise the intimate connexion of anti-social habits with weakness and instability of nervous organisation, is the introduction of hydrotherapeutic methods in association with physical exercises. The Scotch douche, which it is intended to use for this purpose, will be fitted up next to the gymnasium, and it is expected that the installa-

tion will be complete within a very short time.

School instruction and lectures. - The educational attainments of the juvenile-adult prisoners are in general very poor. During the last year for which figures are available the proportion of the boys received into Borstal who had reached the seventh standard was under 2 per cent., and considerably more than a fifth of the whole number were either absolutely illiterate or were only in the first standard. state of things is not due to any innate incapacity, for it is found that these boys learn well and rapidly in prison; their ignorance appears to be another effect of the evil environment in which they have been brought up. This is, in fact, the explanation given with some degree of pride by many London hooligans who boast of their illiteracy as a proof of the success with which they have been able to defy the efforts of the school attendance officers. The importance of providing school instruction for these prisoners is self-evident, even though we do not nowadays attribute to the "three R's" the ethical value formerly ascribed to them; and a good deal of time and effort is given to the matter at Borstal. In addition to the ordinary class instruction, lectures and addresses dealing in a popular manner with scientific and historical subjects are frequently given and are much

liked by the juvenile audience.

Work.—Under the Borstal system special stress is laid on industrial training, not only as a means of increasing the wageearning capabilities of the boys after release, but also as an educative influence of the highest value in correcting the morbidly unstable and spasmodic functioning of the nervous system in these adolescents. The trades taught include smith-work, carpentry, tailoring, bootmaking, building, and farmwork, so that they are of sufficiently diverse character to allow the special aptitudes and tastes of individual boys to be taken into account in selecting the form of labour to which they are to be put. The results appear to be very successful and the work that these young fellows turn out after a few months in the shops is remarkably good. Most of the trade instructors, who, of course, have had experience of ordinary apprentices before entering the prison service, are very emphatic in their opinion of the skill and intelligence shown by the Borstal lads when they have once got into the habit of regular work. The industries which up to the present have been most developed at the reformatory are those in connexion with the building operations actually in progress; the designs have been drawn on simple

given every day with a pièce de résistance which varies; on Sundays it is preserved meat (5 ounces), on Tuesdays and Fridays meat and vegetable soup (1 pint made with 4 ounces of beef, and 2 ounces of split peas or pearl barley), on Wednesdays suet pudding (12 ounces), on Thursdays and Saturdays fresh beef or mutton (5 ounces without bone). We are informed by the medical inspector, Dr. Herbert Smalley, that the average daily ration in this dietary is estimated to give 5.28 ounces of proteid, 17.37 ounces of carbohydrate, 2.39 ounces of fats, and 0.88 ounce of salts, and that its total fuel value amounts to 3259 Calories. The quantity of nutritive material in the Borstal diet is thus a little above Atwater's standard for men doing moderate muscular work; the slight excess, which is chiefly in the proteid constituents, is obviously desirable in view of the special needs of the organism during adolescence. The estimated cost of feeding these prisoners is at the very modest rate of 4.9d. per head per day. The scale is still, of course, fixed in a merely provisional way, and it is quite possible that further experience

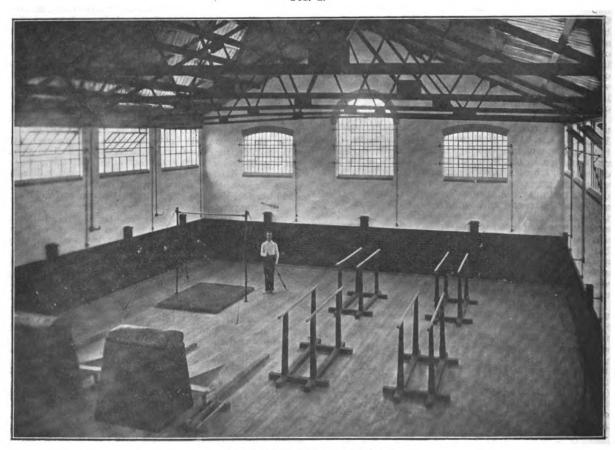

¹ No. I. was published in THE LANCET of Sept. 25th, p. 949.

and straightforward lines so as to enable learners of fair intelligence to carry them out with some skilled assistance; and in this way it has been found possible to execute a large part of the work on the new buildings by the labour of the young prisoners. The brickwork done by the lads looked, at least to the unprofessional eye, quite as good as that laid by contract labour; and the carpentry and metal-work, though, of course, rather rough, seemed to be of very fair quality. The boys for the most part appeared to be genuinely interested in what they were doing and punishment for idleness and inattention is very rarely called for.

Discipline.—The inmates of the reformatory are classified

in three grades—ordinary, special, and penal. On admission the newcomer is placed in the ordinary grade, in which he remains until he has earned promotion by industry and good behaviour to the special grade, or unless he incurs degradation to the penal class on account of misconduct. A prisoner in the special grade enjoys a number of small privileges of the sort that are likely to appeal to a boy's ambition; his cell is better furnished and he is allowed to ornament it with photographs and small pictures sent him by his friends; he has more frequent letters and visits; and he is permitted to associate every day at recreation with others in his grade and to read in his cell for half an hour after the regular bedtime. Prisoners become eligible for promotion to this grade when they have earned a certain number of marks for industry and for conduct, the marks for industry being awarded by the trade instructors and those for conduct by the ward officers under the supervision of the higher officials. A committee, consisting of the governor, medical officer, and chaplain, looks after the working of this system and decides on the fitness of the prisoner for promotion when he has earned the necessary number of marks. This committee has full discretion in deciding whether a prisoner is to be admitted to, or removed from, the special grade. Prisoners who by continued good conduct have retained their position in this grade for several months and who are considered fit for the privilege are allowed to work without being under immediate supervision, or, if shortly due for release, may be employed at labour outside the walls of the reformatory. tinctions are found to create a spirit of healthy emulation amongst the boys; and it is rather interesting to note that they seem to appeal with special force to some of the exleaders of hooligan gangs whose ambitions when at liberty were directed to commanding the "Silver Hatchet" or some similar association of youthful marauders.

After-care. - No scheme for the reclamation of young criminals can be effective without some means of supervision and rehabilitation in honest life after discharge from prison. In the case of the Borstal system this is provided by a body of philanthropic persons known as the Borstal Association, who get into touch with the boys some months before their release and make arrangements for their employment when they come out of prison, keeping an eye on their conduct and giving them advice and assistance during the difficult period of transition from restraint to freedom. The supervision exercised in this way has hitherto been subject to the disadvantage that it was not supported by any power of control over the ex-prisoner's conduct; under the new law this defect has been remedied by the adoption of a system of conditional release on license which may be revoked when the boy's mode of life is not satisfactory. In the future, therefore, the Borstal Association will be in the position of legal guardian to the juvenile-adults on license, and will thus be able to interfere actively when any of its charges show signs of relapsing into the criminal habit. This will be a difficult and responsible work, the successful execution of which will depend very largely on the tact and energy of the voluntary workers who cooperate in it. Fortunately, the indefatigable honorary secretary of the association, Mr. W. Grant-Wilson, seems to have been able to impart a share of his own zeal and enthusiasm to all his coadjutors, so that there is every reason to anticipate that this most important adjunct of the Borstal system will continue to work as satisfactorily as in the past.

The number of prisoners who have been brought under the Borstal discipline is still, of course, comparatively limited, but when adequate reformatory accommodation is available and when the courts begin to make use of the powers conferred by the Prevention of Crime Act a very large number of committals may be expected. The 140 boys now under detention are for the most part London thieves and hooligans. When seen on parade or at work in the shops these youths,

except for their prison dress, are in the lump quite indistinguishable from any scratch collection of adolescents of the urban working class. In the faces of only a very few is there anything in the least suggestive of an inferiority of type; and the medical officer, Dr. A. C. Pearson, who has an intimate knowledge of the lads under his care, considers that it is quite unusual to observe any pronounced stigmata of degeneracy in the young criminals sent to Borstal. This is due no doubt in part to the fact that a good deal of care is taken in selecting the boys who are to be submitted to this treatment, for it is fully realised that the admission of the feeble-minded and the morally idiotic to an institution designed for the training of adolescents of normal aptitudes would imperil the success of the scheme. And here we may note in passing that the Borstal system, by the importance which it thus gives to the preliminary examination into the mental capacity of the juvenile adults at the receiving prisons, is likely to promote very materially that study of individual psychology which is what we most need at present for the advancement of our knowledge of criminal man. When the scheme comes into operation on the larger scale contemplated by the Prevention of Crime Act its influence in this direction will, of course, be proportionately increased, so that, in addition to its intrinsic merits as a method of reformatory discipline, the Borstal system should do much in this country to stimulate the scientific spirit in crimino-

Of course, it is an essential condition of success in any reformatory treatment that it should be applied during a sufficient period of time, and on this account what is termed the "full" Borstal system, such as has been described in this article, is not enforced in the case of prisoners whose sentences are less than 12 months, and under the new Act this is also to be the minimum term of detention in a Borstal institution. It has been felt, however, that some of the Borstal methods, and more particularly the physical training which is an essential feature of the system, might be applied also with advantage to young offenders undergoing shorter sentences, and a modified form of the discipline is accordingly enforced now in the case of all prisoners of juvenile-adult age. It is found that considerable improvement in physique very generally results from this treatment even when its application is limited to a few months: and this is so far satisfactory as showing the promptitude with which these lads react to the healthy influences which are lacking in their normal environment. It is not, however, to be expected that the results achieved in this way can be at all comparable to those obtained from the full Borstal treatment; and it is very desirable that judicial authorities should realise this fact, and that they should come to recognise that, at all events as a general rule, whenever it is necessary to send an adolescent to prison, it is well to send him for a sufficient period of time to enable the corrective influences of this disciplinary system to produce their full effect.

ASYLUM REPORTS.

Cumberland and Westmorland Lunatic Asylum (Report for the year 1908).—The average number of patients resident for 1908 was 803, of whom 415 were men and 388 were women. The direct admissions numbered 170, and nine persons were admitted from other asylums. number of patients discharged was 79, and of these 60 were recovered and 19 relieved. The proportion of recoveries calculated on the number of direct admissions was 40.6 per cent. Deaths numbered 68 and the death-rate, calculated on the daily average number resident, was 8.3 per cent. Dr. W. F. Farquharson, the medical superintendent, draws attention to the importance of the findings of the Royal Commission on the Care of the Feeble-minded. By the suggested provisions of that Commission all mentally defective persons would be kept under proper control and supervision, trained to do useful work, and, if necessary, kept permanently apart from the rest of the community. The cost of the scheme would at first be great, but there can be no doubt that its adoption would be of benefit to the community and would eventually lead to a saving to the ratepayers.

Lincolnshire County Asylum, Kesteven (Report for the year 1908).—To this asylum 75 cases were admitted, 66 of these being direct admissions. The total number of patients

under treatment during the year was 448. 37 patients were discharged, of whom 27 had recovered, giving on the direct admissions nearly 41 per cent. of recoveries. Deaths numbered 31, which gives a percentage of 8·13, calculated on the average number resident. The average age at death was 58. It appears that hereditary predisposition was even more frequently assigned as a cause of illness than in past years, and in over 50 per cent. of those admitted this factor had to be taken into account.

Asylum for the Counties of Salop and Montgomery and for the Borough of Wenlook (Report for the year 1908).—
During this year 976 patients were under treatment. The admissions numbered 197; of these 48 were readmissions and 96. Of these 74 were discharged recovered, and of these patients 76 per cent. had been resident for less than 12 months. The deaths were 75 in number, the percentage on the average number resident being 9.49. At the end of the year there were resident 29 more patients than accommodation was provided for, and in addition to this a large number of patients have had to be boarded out. It appears, however, that the problem of providing further accommodation in the asylum itself is no nearer solution, as the proposed purchase of the Copthorne estate for this purpose has been vetoed by the Secretary of State.

Nottingham City Asylum, Mapperley Hill (Report for the year 1908).—The average daily number resident at this asylum for last year was 827. There were admitted during the year 171 patients. The discharges numbered 103, of whom 64 had recovered, this giving a percentage of 39 on the admissions. Deaths numbered 80, giving a percentage of 9.6 of the average number resident. It appears that the number of senile cases admitted was comparatively great, 18 persons being above 65 years of age. Mr. Evan Powell, the resident medical superintendent, writes that it might be regarded as absurd and wrong to send such cases to an asylum, but that as a fact such patients constitute a troublesome class requiring the constant attention of the nurses, and that at present the only alternative to keeping such persons at home is to place them in an asylum. The workhouses may be said to be the proper place, but the workhouses have not the requisite staff or the accommodation.

Hertfurdshire County Asylum, Hill End, St. Albans (Report for the year 1908).—At this asylum the total number of cases under treatment was 717. There were 145 admissions, of whom 81 were first attack cases. The discharges numbered 50, of whom 42 were discharged recovered. The recoveries from cases directly admitted numbered 39, and the proportion this number bears to the number of direct admissions is 29·1 per cent. The deaths numbered 43, being a percentage of 7·12 on the average daily number on the register. The extension works were completed in March last and give accommodation to 234 patients.

Barnsley Hall Asylum (Report for the year 1908). The total number of cases under treatment at this asylum was 514. The admissions numbered 230, and Dr. P. T. Hughes reports that the character of the cases admitted was such that the prospect of recovery appeared unusually un-favourable. More than one-third of the first attack cases were aged 60 years and upwards and six were over 80 years of age. The unsuitability of many of the cases which are at the present time sent to asylums because there is no proper accommodation for them elsewhere has been referred to by the Commission upon the Feeble-minded. The report of that Commission says: "We find lunatic asylums crowded with patients who do not require the careful hospital treatment that well-equipped asylums now afford and who might be treated in many other ways more economically and as efficiently." Dr. Hughes further points out that defective heredity being so potent a factor in the causation of insanity it has become a serious and difficult problem as to how best to cope with the evil. "The physiological laws which govern the reproduction of sound stock are the same for both man and animal, yet few of the elaborate precautions taken to secure sound pedigree stock find a counterpart in the reproduction of the human race. Sentimental and legal reasons insist upon the discharge of individuals from asylums as 'recovered,' who appear to be sane whilst surrounded by the specially adapted asylum environment but who are really deficient and unfitted to be the parents of children. It is a

matter for very serious consideration whether any patient who has had more than one mental breakdown should be given a further opportunity of reproducing defective stock." The discharges numbered 57, and the rate is low owing to the unfavourable character of the admissions. The total number of deaths was 51.

POOR-LAW AND HOSPITAL PROBLEMS IN THE SIXTEENTH CENTURY.

THERE are two problems which are much to the fore to-day, and those two closely related-namely, relief of the poor, with which may be placed Poor-law problems, and the question of hospital abuse. It is interesting to note that these two problems were a matter of nearly as much concern to the sixteenth century as to our own. Robert Copland, a printer and author who flourished 1508-1547, wrote among other poems a piece called "The Hye Way to the Spyttell Hous," which is cast in the form of a dialogue between himself and the porter of a hospital, which from internal evidence would appear to be that of St. Bartholomew. Copland begins by saying that "about a fourtenight after Halowmas" he chanced to come by a certain spyttel where, as it was raining and snowing, he thought it best to take shelter in the porch. And as he stood there the porter of the house stood by him. They conversed, and it is pleasing to note that even then, like true Englishmen, their conversation began on the subject of the weather, "with whom I reasoned of many divers things, touching the course of all such wetheringes," says Copland. As he stood there—

"....... there gathered at the gate
People as me thought of every poore estate,
With bag and staf, both croked lame and blind,
Scabby and scurvy, pocke eaten flesh and rynde,
Lowsy and scalde, and pylled like as apes,
With scantly a rag for to cover theyr shapes,
Brecheles, barefoted, all stynkyng with dirt
With M.¹ of tatters drabblyng to the skirt,
Boyes, gyrles and luskysh strong knaves,
Dydderyng and dadderyng, leaning on their staves
Saying: gode master for your moders blessing
dive us a halfpenny toward our lodging."

Thereupon the porter rebuked them for begging, telling them-

"Ye shall be entreated as ye ought to be, For I am charged that dayly to see The systers shall do theyr observaunce As of the hous is the due ordinance."

Copland then inquired if everyone who applied was taken in, and was especially curious about the vagrants whom he said that he was in the habit of seeing when he went out with the watch: "I wot not whether they be thieves or hoores," but whom he found full oft at the door of Saint Barthylmews Church, "or in the shepe cootes or even here always by this bricke wall," and who "oftentimes that they us se, they do rene a great deal faster than we." The porter replied that such were certainly not taken in. Copland then inquired who were relieved, and the porter answered:—

"Forsoth they that be at such myschef
That for their lyving can do no labour,
And have no frends to do them socour,
As old people, seke and impotent,
Poore women in childbed here have casement,
Weyke men sore wounded by great vyolence,
And sore men eaten with pockes and pestylence,
And honest folk fallen in great poverty
By myschance or other infirmity;
Wayfaryng men, and maimed soldyours,
Have theyre reliof in thys poore hous of ours,
And all others which we seme good and playne,
Have here lodging far a nyght or twayne

But not every unseke stoborn knave For then we should over many have."

It will be seen from this that in these days St. Bartholomew's fulfilled the double office of a hospital in the modern sense and of a Poor-law infirmary or casual ward. Care, however, was taken to keep out the impostors about whom Copland next asked, for the porter said, "No in soth, this hous is of no such supporter." And he proceeds to give a delightful account of such impostors, from which it will be seen that the art of counterfeiting disease is no new thing, although

within the last 50 years the action of the Mendicity Society has put an end to the frauds described below. Some beggars

"dyssymule as false lewtring flowches
With bloody clowtes all about theyre legge
And playsters on theyre skyn when they go beg,
Some counterfayte lepry, and other some
Put som in theyre moth for to make it scome
And fall down as St. Cornelys evyl,
These devecyts they use worse than any devyll,
And when they be in theyre own company
They are as hole as either you or I."

The counterfeiter of epilepsy with soap in his mouth was a familiar object at the Strand end of Waterloo Bridge some 40 years ago, if we remember right, but he used to vanish with alacrity on the approach of a policeman.

But at the last the hospital is open even to these, "whan sekenes cometh in dede, Than to the spyttell house must they come nede." Copland next inquires after the masterless men who have served the king beyond the sea and are now "out of wages," cannot they be helped till they get some work? The porter agrees, but says that most of them are vagabonds who will not do steady work, and he implies that most of them have never been in the army at all. He then goes on to describe other varieties of tramps, beggars, and impostors, and at length comes to the quack. He pretends that he cannot speak English: "Me non spek Englys by my fayt, my servant spek you what me says." He feigns marvellous gravity, and people naturally ask whence he comes. Then the servant answers "that he was born in heathenesse and is a cunning man,

"For all the seven scyences surely he can And is sure in physik and palmestry, In augury, sothesaying and vysenamy." So that he canright sone espy If ony be disposed to malady, And therfore can give such a medicine That maketh all accesses to decline."

So great a man, however, cannot be expected to meddle with the diseases of common people, and if it were known that he did he would lose "the favour of every great estate." Still he will treat poor persons out of charity, taking no money. He is described as looking at a child and saying, "Dys infant rumpre ung grand postum, By got he ala mort tuk under tum." This the servant translates into the statement that the child has a bag in his stomach as great as he may wag, that within two or three days it will choke him, and that unless they take the physician's advice the child will "sodenly be dede." The mother offers 20s. but the quack refuses any fee.

"Then calleth he anon for hys casket That scantly is worth a rotten basket, And taketh out a poudre of experience That a cartlode is not worth twopence."

This powder is to be taken fasting during three days. He then departs without taking any money. The next day a confederate turns up and seeing the child informs the mother that it will be dead within three days, "but oure Lord hym save." The mother struck by this remark says that only yesterday a gentleman had told her the very same thing. Whereupon quack number two inquires what sort of man it was. On his being described he says that he knows him well and wonders that he brought himself to prescribe for such a mean household. The mother then begs her visitor to prescribe and offers 20s. and expenses for a week or two. The quack replies that he will take no money for his labour but that his drugs must be paid for and they are very expensive. Moreover, he will stop in the house until the child be whole.

"Than gooth hys knave to the town to buy
These dragges that be not worth a t—de,
And there they lie at fourtenight at borde
With these good folkes, and put them to coste,
Both mete and money"

At the end of the fortnight the quack rejoins his fellow rogue and they make merry with the twenty shillings. For such men as these, says the porter, "The spyttell is not for theyr estate, Howbeit they come dayly by the gate."

Copland then asks "of all folk in general that come the hye way to the hospytall." The porter answers that the list is tedious, a remark with which the reader might agree, racy as our author is, if we quoted the whole passage. But, shortly, it amounts to the fact that all persons who do not do their duty in this life—gamblers, spendthrifts, wastrels, tramps, cheating tradesmen-" must needs come this way." After this tragic passage, which shows the hospital in its character as a poor house, we have a piece of comedy. Copland asks,

"Come hither any of these wofull creatures
That be sore wounded and much we endures
With a shrewd wyfe, and is never quiet
Bycause that she wold have all her dyet
But bralle and chyde, babble crye and fight,
Ever uncontented both day and nighte?"

Porter: 'Come thys way, quod a?' Yes I warraunt you
Of them always come thys way enow,
We have chambres purposely for them,
Or else they should be lodged in Bedlem.'"

He adds that, in his opinion, the very devil in hell has not so bad a time as a husband and wife who are always quarrelling.

Other varieties of rogues are mentioned whom the hospital "must receyue and give them costes free" and the porter concludes (for the time being) his list of applicants by the following lament which will strike a sympathetic note in the hearts of Cabinet Ministers,

"Of all the sortes that be spoken of afore I warraunt women enow in store That we are wery of them: euery day They come so thycke that they stop the way."

Copland then says that as it is fine he will now go, and thanks the porter for his information, to which that indefatigable official says,

"There be a M. more than I can tell But at thys time I bid you farewell."

So ends this curious little tract, a work which shows that the problems which now exercise Poor-law experts are no new The loafer, the criminal, the tramp, the vagrant, and all those who, as Copland says-

"All the somer keep dyches and buskes
And will not work but the bypaths trace
And live wyth hawes and hunt the blakbery
And wyth hedge breking make themself mery
But in wynter they draw to the towne,"

Are these, he says, to find shelter?

"Me think that therein ye do no right Nor all such place of hospytalyte To comfort people of such iniquity."

Further on he refers to the Act recently passed against vagabondage, probably that of 1531, and argues that if it were put in force the quantity of beggars would not be so great. That Act allowed certain people to beg under license, but sturdy and valiant beggars were to be whipped at the cart tail. Scholars of Oxford or Cambridge were not to beg without license from the Chancellor or Vice Chancellor under penalty of whipping. Pardoners, proctors, and other rogues, especially those who pretended to have a knowledge of physic, were likewise to be whipped, and on a second offence were to have an ear cut off after a double whipping. The reader who scans the advertisement pages of the popular magazines of to-day may well wish that some such enactment were in force now. Verily the problem of what to do with the unemployable, of the "born tired," and of the loafer is as old as civilisation.

² The word "proctor" in this connexion did not, of course, mean the University official representative of the Masters, but one who collected alms for lepers and others unable to beg in person. Within a few years, however, the word practically meant any kind of beggar who lied. In this connexion Watts's Charity at Rochester, well known to all readers of Dickens, may be quoted. The inscription over the door runs :--

RICHARD WATTS, Esq.
by his Will, dated 22 Aug. 1579,
founded this Charity
for Six poor Travellers,
no not being ROGUES, or PROCTORS,
May receive gratis for one Night,
Lodging, Entertainment,
and Four-pence each.

St. Mary's Hospital Medical School (Uni-VERSITY OF LONDON) .- As a result of the September examinations the following gentlemen have been elected to entrance scholarships subject to confirmation by the governing body of the Medical School: University scholarships: 50 guineas, Horatio Thomas, University College, Cardiff; 50 guineas, T. H. Phillips, University College, Cardiff. Open scholarships in Natural Science: £145, R. W. Davies, King Edward's School, Birmingham; £50, F. W. MacAlevey, Mount St. Mary's College, Chesterfield; £25, J. E. Cheesman, South-Western Polytechnic. Epsom College scholar-ship: D. R. Alexander.

Public Bealth.

REPORTS OF SCHOOL MEDICAL OFFICERS.

The City of Liverpool.—The health conditions of the school children of Liverpool present a special interest by virtue of the fact that in certain parts of the city numerous racial elements are commingled, the Jewish and Polish quarters being both large and increasing. The question of race is being inquired into in the case of each inspection, and it is not unlikely that when sufficient data have been acquired some interesting facts may be revealed, although, of course, the foreigners who settle in Liverpool may be either the fit or the unfit representatives of their respective nations. It is somewhat difficult to determine which, because no doubt different forces are at work inducing emigration in different countries. It is difficult, for instance, in the case of England to determine whether it is the fit or unfit which leave the country. As regards Ireland, it is thought by many that it is the fit which depart, thus leaving behind the unfit to alter what might be regarded as the normal relations between the healthy and the unhealthy. In the case of Liverpool it is obviously necessary to determine the nationality of the children in order to establish a sound basis upon which to build up inquiries as regards national deterioration. The first report to the Liverpool education authority is made by Dr. E. W. Hope, the medical officer of health, and we are glad to see that the general supervision of the procedure has been left in his hands. The actual work of inspection is carried out by three medical officers, and with the consent of the health committee the services of its female sanitary inspectors have been placed at the disposal of the school medical officers. There are at the present time 14 of these inspectors, who have definite districts of the city assigned to them, and whose services are made use of when the schools in their districts are being inspected. These female inspectors also visit at their homes such children as the medical officers deem desirable, and as it is the duty of these inspectors to put into force Section 122 of the Children Act, 1908, which deals with verminous children, there is an obvious advantage in this arrangement. With regard to clothing, the inspections brought out the fact that 12 per cent. of the children possessed no underwear at all, and it was found that in the poorer neighbourhoods the children wear practically the same number of garments both in summer and winter. About 60 per cent. of the children were wearing watertight boots, 10 per cent. had boots with mere apologies for soles, another 25 per cent. boots which although satisfactory in dry weather were not watertight, while the remainder came barefooted to school. As to nutrition, 20 per cent. of the new admissions were good, 55 per cent. fair, 23.5 per cent. poor, and 1.5 per cent. bad, and in each case the condition of the girls was rather better than that of the boys. But it must be borne in mind that it was children from the poorer parts of the city that were here under examination. During the autumn of 1908 an inquiry was made by the medical officer of health as to the extent to which under or improper feeding prevailed in Liverpool, and on consideration of the reports made the city council decided not to put in force during the winter the Education (Provision of Meals) Act, 1906, but to rely upon voluntary contributions which were administered by a special subcommittee of the education committee. Coupons available at cocoa-rooms and a few special depôts were given to the children who required food, and a marked improvement in the physical and mental condition of the children was noted by the teachers. Large numbers of children appear to have been fed by the committee during the winter months, and, in addition, some 2000 were receiving meals every day at the day industrial schools and at special schools. The result of the investigations at the homes of the children was to show that amongst a great number of the very poor the diet consisted of bread and butter and tea for each meal, occasionally, in some cases, varied by fish or "hot-pot," but in many instances the family had nothing but bread and thea. In the case of the children from some schools it was found that although the parents could afford to provide them with good food their ignorance was responsible for the insufficiency of nourishment. The above facts bring out very clearly the enormous importance of the inspection of school children and of the visits of

educated persons to the homes. If those people who, with insufficient food, drink tea in excess could only be induced to procure milk instead, this act in itself would constitute an enormous advance. Enlarged cervical glands were noticed in as many as 22 per cent. of the new admissions, and in 12.5 per cent. of those finally leaving school, but in only two cases altogether could such glands be definitely called tuberculous. Similarly, there were but six cases of pulmonary tuberculosis amongst all the children examined. With respect generally to the question of treatment no arrangements have as yet been made with any of the general or special hospitals or the dispensaries, but a special subcommittee has been formed to consider the question, at least

so far as defective eyesight is concerned.

The West Riding of Yorkshire.—The inspection of the children in this important county is carried out by ten whole-time medical inspectors acting under the supervision of the county medical officer of health, Dr. J. R. Kaye. The question of employing as inspectors all the 111 local medical officers of health (mostly in private practice) was in the first instance considered, and it was only after holding a general conference of such medical officers of health that the arrangement already referred to was decided upon. There are ten districts, for each of which a resident medical inspector, who devotes the whole of his time to the work, has been appointed, and the number of children on the register of each district varies from 10,000 to 31,604. Up to the present no school nurses have been appointed, but it is anticipated that such appointments may be desirable in the future. The parents do not as yet appear to have taken a very active interest in the process of inspection, as although notifications were sent to all in the usual fashion only 14.05 per cent. were present at the inspection of their children. But it is necessary to point out that, owing to unavoidable delays, the figures given only relate to the last three months of 1908; in other words, the current report must be regarded as rather a preliminary and preparative one than an annual report. Moreover, the figures here furnished should not be used as the basis for any general inferences. Of the children examined only 0.57 per cent. were regarded as "poorly nourished"—a term which, it is pointed out, is not synonymous with "poorly fed"; but as there were no weighing machines available it was difficult to arrive at very accurate results. Some apparent anomalies as regards nutrition were found in different districts. For example, Dr. Elizabeth M. McVail, one of the medical inspectors, found in her district that the nutrition of the children seemed better in the valley schools than on the hillsides, but she thinks that the explanation may be found in the fact that the average wage of the valley residents is higher than that of those living on the hill-sides. As regards the Huddersfield area, Mr. G. H. Pearce states that he found no children who could be properly regarded as poorly nourished, in explanation of which he points to the absence of real poverty in the villages visited by him, and in his view the children are much better nourished than is the case in the urban districts. Dr. Eva McCall, writing as to the Barnsley district, finds the economic conditions there prevailing largely responsible for the high standard of nutrition which obtains. The miners are well paid and there is no demand for female labour. Consequently the woman attends to her home and to her children. As the statistics in this report refer to such a brief period it will be better to defer detailed consideration of this side of the West Riding report until next year. In the matter of treat-ment it has been decided in the first instance, in addition to the usual advice to parents, to form what are known as local "care of children" committees. So far as we are able to gather, it is proposed that these committees should be composed partly of co-opted ladies and that such committees should endeavour, somewhat on the lines of the Elberfeld relief system, to take a personal interest in certain cases and bring them in touch with philanthropic and other institutions. We look forward to next year's report to hear what success has attended the work of these committees.

Borough of Bootle.—The first annual report to the education committee of this borough is made by Mr. W. Daley, who is the medical officer of health and who receives an additional £25 per annum in consideration of his work in connexion with school inspection. His specific duties are (a) to supervise such medical assistance as may be necessary; (b) to present an annual report; (o) to take steps as regards

infectious disease; (d) to report as required on the sanitary condition of schools; and (e) to attend meetings of the The actual work of inspection education committee. devolves upon the additional medical officer, who receives £150 per annum for such work and who, for additional remuneration, acts as surgeon to the police and the fire brigade. During the year 1908 there were 1565 children examined, and in 60 per cent. of the examinations the parents accepted the invitation to be present. As regards treatment it is stated that, speaking generally, the parents of the poorer children do not carry out the advice of the school medical officer in cases where any financial outlay would be involved, but parents better circumstanced have to an appreciable extent either consulted their own medical adviser or taken the children to a hospital. But the figures relative to certain diseased conditions are far from satisfactory. Of 406 cases of enlarged tonsils and adenoids only 11 cases received treatment. Enlarged oervical or submaxillary glands were detected in 181 cases, a large proportion being due to verminous conditions or decayed teeth. As regards dental conditions 20 per cent. of the children were found to present some defects, while in the matter of clothing 16 per cent. were found to be badly clothed or badly shod. Of the total number of children examined eight were found to be suffering from pulmonary tuberculosis. In the matter of general nutrition many of the children were found below the normal standards of height and weight, but the report states that the majority of these were simply undersized children well nourished and cared for. No open-air camps have as yet been arranged for, but in the summer, in fine weather, classes are held in the playgrounds. Of the children attending school there had suffered before the commencement of school life 58 per cent. from measles, 36 per cent. from whooping-cough, 18; per cent. from chicken-pox, 7½ per cent. from scarlet fever, and 1½ per cent. from diphtheria.

County Borough of Devonport.—Mr. O. Hall, the medical officer of health, has been appointed school medical officer for this district. Out of 2078 children examined 44.8 per cent. had good teeth, 24.6 per cent. indifferent, and 30.7 per cent. bad, and Mr. Hall suggests that a tooth-brush drill should be introduced into the school curriculum. Pulmonary tuberculosis was found in only eight cases, although predisposing conditions were frequent. Nutrition was on the whole satisfactory. The subject of treatment is not discussed in any detail; probably the experience of the first year is being awaited.

Borough of Cambridge.-The work of the medical inspection of school children was commenced in voluntary fashion in Cambridge in 1907, but the advent of the compulsory régime has necessitated rearrangement of the whole procedure. The school medical officer is Dr. A. J. Laird, the present medical officer of health, who has himself carried out the medical inspection, and a school nurse, who was appointed in the autumn of 1906 at a salary of £95, assists at the inspection by weighing and measuring the children and by testing their hearing and vision. She also follows up cases at their homes and reports in writing to the school medical officer. A dentist has also been provisionally appointed at a salary of £300 per annum, but it appears that at the date of making the report the appointment had not received the sanction of the Board of Education. Assistance at the routine inspection is also afforded by three lady health visitors, who in addition follow up cases at their homes. As regards routine inspection it is not the practice at Cambridge to invite the attendance of the parents, although they are informed by the teachers that their presence will be welcomed. Notices are, however, sent to the parents whose children present defects requiring attention, and this notice is followed by visits from the school nurse or health visitors. The figures as regards nutrition were as follows: above average, 15 per cent.; average, 68 per cent.; below average, 17 per cent.

County Borough of Bournemouth.—Dr. A. D. Edwards, who is the school medical officer of the borough, reports that as the work of inspection was not commenced until October, 1908, the report deals mainly with local conditions of school hygiene upon which sufficient information for trustworthy deductions has been obtained. We gather that Dr. Edwards is not altogether satisfied with the present arrangement, by which he as school medical officer does not form part of the public health service of the town, and he thinks that under

the system which at present obtains there is always the possibility of the existence of an undesirable gap between the work of the departments. It is not clear why the town council in the first instance decided to keep the work of medical inspection outside that of the medical officer of health. The attendances of parents at the medical inspections of the children vary widely. Sometimes it is as high as 60 per cent. and at other times it is as low as 6 per cent. In the matter of treatment Bournemouth seems somewhat badly provided, there being no provision for the treatment of defective vision, enlarged tonsils or adenoids, diseases of the throat, ear, or nose or carious teeth, and Dr. Edwards states that in none of these conditions is it possible for the parent to obtain adequate treatment for the child at a small charge from a medical practitioner. This is an unfortunate state of affairs, and in the interest of the public health it ought somehow to be remedied. The past incidence of infectious diseases upon children leaving school before August, 1909, was as follows: measles, 86 56; whoopingcough, 37.5 per cent.; chicken-pox, 20 per cent.; and scarlet fever, 2.5 per cent. In cases of the suspected occurrence of infectious disease amongst the scholars swabs from the throat are taken for bacteriological examination and by this means symptomless "carriers" have been excluded. Children are always excluded from school when the true Klebs-Löffler bacillus is detected, but the presence of Hoffman's bacillus is not regarded as warranting such exclusions. But where this bacillus is found the children harbouring it are regarded with suspicion. In one instance where typical Klebs-Löffler bacilli had been found in the throat swabs the pencils which had been used in common by the children in the affected class were examined and the typical organisms found. Dr. Edwards urges the reinstatement of the epidemic grant which was withdrawn in 1903.

VITAL STATISTICS.

HEALTH OF ENGLISH TOWNS.

In 76 of the largest English towns 8004 births and 3974 deaths were registered during the week ending Sept. 25th. The annual rate of mortality in these towns, which had been equal to 12.8 and 13.0 per 1000 in the two preceding weeks, declined to 12.6 in the week under notice, and was lower than in any week since the middle of August. During the first 12 weeks of the third quarter of the year the annual death-rate in these towns averaged only 11.9 per 1000, and in London during the same period the rate did not exceed 11.4 per 1000. The lowest annual rates of mortality recorded in the 76 towns last week were 4.0 in Lorton 4.5 in King's Norton 4.0 in Homeon and 5.0 in Leyton, 4.5 in King's Norton, 4.9 in Hornsey, and 5.9 in West Hartlepool; the rates in the other towns ranged upwards, however, to 16.7 in Hull, 17.4 in Rochdale, 17.5 in Oldham, and 17.8 in Middlesbrough. In London the recorded death-rate last week was equal to 12.2 per 1000. The 3974 deaths in the 76 towns last week showed a decline of 127 from the number in the previous week, and included 509 which were referred to the principal epidemic diseases, against numbers declining steadily from 849 to 632 in the four preceding weeks; of these 509 deaths, 348 resulted from diarrhoea, 51 from whooping-cough, 37 from diphtheria, 30 from measles, 26 from scarlet fever, and 17 from "fever" (principally enteric), but not one from small-The 509 deaths from these epidemic diseases last week were equal to an annual rate of 1.6 per 1000, a lower rate than in any week since the middle of August. No death from any of these epidemic diseases was registered last week in Cardiff, Leyton, Halifax, Hornsey, or in five other smaller towns; the annual death-rates therefrom ranged upwards, however, to 3.5 in Rhondda and in Middlesbrough, 3.8 in Hanley, 4.0 in Brighton, and 4.9 in Stockton-The deaths attributed to diarrhoea in the on-Tees. 76 towns, which had declined in the four preceding weeks from 676 to 461, further fell last week to 348, but eaused annual death-rates ranging upwards to 2.8 in Hull, 2.9 in Stockton on-Tees, 3.0 in Middlesbrough, 3.1 in Rhondda, and 3.2 in Brighton. The fatal cases of whoopingcough, which had been 73 and 59 in the two previous weeks, further declined to 51 last week; the highest annual rates from this disease being 1.2 in Derby and 2.0 in Great

further decline from the numbers returned in recent weeks, but caused annual rates equal to 1.3 in Coventry and in Newport (Mon.), and to 2.3 in Hanley. The 37 fatal cases of diphtheria, however, showed a distinct increase on recent weekly numbers, and included 18 in London and its suburban districts and three in Portsmouth; this disease caused deathrates last week equal to 1.3 in Devonport and 1.4 in Warrington. The 23 deaths from scarlet fever slightly exceeded the number in the previous week; 11 occurred in London and its suburban districts, six in Manchester and Salford, and two in Birmingham. The deaths referred to "fever," which had been 14 and 30 in the two preceding weeks, declined again to 17 last week, and were considerably below the corrected average in recent years. The number of scarlet fever patients under treatment in the Metropolitan Asylums and the London Fever Hospitals, which had steadily increased in the four preceding weeks from 2347 to 2553, had further risen to 2686 on Saturday last; 438 new cases of this disease were admitted to these hospitals during last week, against numbers increasing steadily in the five preceding weeks from 245 to 421. Of the 1127 deaths registered in London last week, 149 were referred to pneumonia and other diseases of the respiratory system, against 105 and 130 in the two preceding weeks, and exceeded by two the corrected average number in the corresponding week of the five years 1904-08. The causes of 31, or 0.8 per cent., of the deaths registered in the 76 towns last week were not certified either by a registered medical practitioner or by a coroner. All the causes of death registered during last week were duly certified in Bristol, West Ham, Newcastle-on-Tyne, Hull, Nottingham, Leicester, Salford, and in 50 other smaller towns; the 31 uncertified causes of death in the 76 towns last week included nine in Liverpool, three in London, and two both in Birmingham and in Reading.

HEALTH OF SCOTCH TOWNS.

In eight of the principal Scotch towns 810 births and 494 deaths were registered during the week ending Sept. 25th The annual rate of mortality in these towns, which had been equal to 13.8, 12.3, and 12.1 per 1000 in the three preceding weeks, rose again to 13.8 in the week under notice. During the first 12 weeks of the past quarter the deathrate in these Scotch towns averaged 12 6 per 1000, and exeeeded by 0.7 the mean rate during the same period in the 76 large English towns. The annual death-rates last week in these Scotch towns ranged from 10.1 and 10.9 per 1000 in Greenock and Edinburgh, to 17.7 in Leith and 19.8 in Perth. The 494 deaths from all causes in the eight towns showed an increase of 63 upon the number returned in the previous week, and included 52 which were referred to the principal epidemic diseases, against 71, 56, and 47 in the three preceding weeks. These 52 deaths were equal to an annual rate of 1.5 per 1000, which was slightly below the mean rate from the same diseases in the 76 English The 52 deaths from these epidemic diseases last week included 20 from diarrhœa, nine from "fever," eight from diphtheria, seven from scarlet fever, five from whooping-cough, and three from measles, but not one from small-pox. The deaths attributed to diarrhoea in the eight towns, which had steadily declined in the four preceding weeks from 47 to 25, further fell last week to 20, of which 11 occurred in Glasgow, four in Dundee, and three in Leith. The nine deaths referred to "fever" showed a marked increase upon the numbers in recent weeks, and included six in Glasgow and one each in Dundee, Aberdeen, and Leith; seven of the nine were certified as enteric fever, and the other two (including one each in Glasgow and Aberdeen) as cerebro-spinal meningitis. The eight fatal cases of diphtheria included seven in Glasgow and one in Dundee; and of the seven deaths from scarlet fever four were returned in Edinburgh and two in Glasgow. The five fatal cases of whooping-cough corresponded with the number in the previous week, including three in Glasgow and two in Edin-burgh; and two of the three deaths from measles were returned in Glasgow. The deaths referred to diseases of the respiratory system in the eight Scotch towns, which had been 25 and 41 in the two preceding weeks, further rose to 59 last week, and corresponded with the number in the corresponding week of last year. The deaths in these eight towns last week included 22 which were referred to different forms of violence, of which 14 occurred in Glasgow and three in Dundee. The causes of 13, I the House of Commons on Sept. 28th regarding the number

or 2.6 per cent., of the deaths in the eight towns last week were not stated or not certified; in the 76 English towns the proportion of uncertified causes of death last week did not exceed 0.8 per cent.

HEALTH OF DUBLIN.

The annual rate of mortality in Dublin, which had been equal to 16.8 and 17.3 per 1000 in the two preceding weeks, further rose to 19.5 in the week ending Sept. 25th. During the first 12 weeks of the past quarter the death-rate in the city averaged 17 2 per 1000, whereas the mean rate during the same period did not exceed 11 4 in London and 12.2 in Edinburgh. The 149 deaths of Dublin residents during last week showed a further increase of 17 upon the number returned in the two preceding weeks, and included 10 which were referred to the principal epidemic diseases, against numbers declining steadily in the four preceding weeks from 37 to 12. These ten deaths were equal to an annual rate of 1 3 per 1000, the death-rate from the same diseases last week being 1.7 in London and 1.2 in Edinburgh. Of these ten deaths from the principal epidemic diseases in Dublin last week, six resulted from diarrhea, two from diphtheria, and one each from scarlet fever and "fever," not one from measles, whooping-cough, or small-pox. The six fatal cases of diarrhœa corresponded with the number returned in the previous week. Of the 149 deaths at all ages in the city last week 34 were of infants under one year of age, and 40 of persons aged upwards of 60 years; the deaths both of infants and of elderly persons showed a considerable increase upon the numbers returned in the two previous weeks. Two inquest cases and two deaths from violence were registered during the week, and 50, or 33.6 per cent., of the deaths occurred in public institutions. The causes of two, or 1.3 per cent., of the deaths in Dublin last week were not certified either by a registered medical practitioner or by a coroner; in London the proportion of uncertified causes of death did not exceed 0.3 per cent., while in Edinburgh it was equal to 4.0 per cent.

THE SERVICES.

ROYAL NAVY MEDICAL SERVICE.

THE following appointments are notified: -Staff-Surgeon: H. J. Chater to the Vernon, additional, for the Furious. Surgeon: A. V. J. Richardson to the Hindustan, on recommissioning.

SPECIAL RESERVE OF OFFICERS.

Royal Army Medical Corps.

Supplementary list: Thomas McEwen to be Lieutenant (on probation) (dated August 13th, 1909).

TERRITORIAL FORCE.

Royal Army Medical Corps.

2nd London Sanitary Sompany: Captain Peter Caldwell Smith to be Major (dated Sept. 8th, 1909).

Attached to Units other than Medical Units. - Lieutenant Alexander C. Farquharson to be Captain (dated August 17th, 1909). Lieutenant Henry L. Gregory to be Captain (dated August 24th, 1909).

For Attachment to Units other than Medical Units.—George Brittan Gill to be Lieutenant (dated August 25th, 1909). Surgeon-Captain John A. Kendall from the 9th Battalion, The Durham Light Infantry, to be Captain (dated Sept. 1st, 1909).

Infantry.

5th Battalion, The Sherwood Foresters (Nottinghamshire and Derbyshire Regiment): Surgeon-Major Edmund Vaudrey resigns his commission, and is granted permission to retain his rank and to wear the prescribed uniform (dated August 24th, 1909).

VOLUNTEERS.

Royal Garrison Artillery (Volunteers).

1st Carnarvonshire: Surgeon-Lieutenant-Colonel and Honorary Surgeon-Colonel Edward J. Lloyd resigns his commission, and is granted permission to retain his rank and to wear the prescribed uniform (dated March 31st, 1908).

TUBERCULOSIS OF THE LUNG IN THE ARMY.

Mr. Haldane, in reply to a question by Mr. Summerbell in

of soldiers that have been discharged from the army during the ten years ending 1908 suffering from tubercle of the lung, said:—The number of men so discharged were as follows: 1899, 224; 1900, 328; 1901, 350; 1902, 334; 1903, 301; 1904, 440; 1905, 333; 1906, 400; 1907, 304; 1908, 272. While in hespital patients were kept apart from other patients and treated generally as cases of infectious disease. On discharge a notification was sent to the medical officer of health in the town or district where the man proposes to reside.

Correspondence.

"Audi alteram partem."

REMINISCENCES OF CHOLERA.

To the Editor of THE LANCET.

SIR, -I have just read with great interest in THE LANCET of Sept. 25th, p. 948, a letter under "Looking Back" entitled "A Severe Case of Cholera," and contributed to your columns 78 years ago by Mr. J. Burgess, apothecary to St. Giles's Workhouse. I believe it must be the description of a case illustrated by a picture which was so strikingly real that I kept the volume of THE LANCET containing the picture always at hand so as to be able to show it to any friends who had never seen a patient with this fearful disease. I always thought it was a sketch by the doctor of some miserable room or attic in which the poor woman lived, and probably at Sunderland where the disease first broke out. If I remember right there was only one chair in the room, a kettle on the fire, and the patient lay stretched out on a bed with only a slight garment on to cover her; the hands and feet, which were exposed, were quite blue, as was also the face. She had the ghastly look which the doctor so well describes. I should think from his remarks that he did not regard the case in any other light than a very severe form of the autumnal disease well known in England, and with which he was no doubt familiar. I myself, however, am of opinion that it was an example of the Asiatic cholera which had just arrived at our shores. Everyone has occasionally seen severe cases of English cholera where all the symptoms of the malignant form had been reached. There are also other cases caused by poison and by food resembling it. I once met with a severe case of the latter where scarcely a symptom of cholera was wanting. It was that of a gentleman who thought he should like to taste some sturgeon which he had seen in a fishmonger's shop. He ate heartily of this for his dinner, and soon after he began to vomit; then he was violently purged, and finally he experienced most agonising cramps in the legs; he became cold and almost pulseless. His wife was telegraphed for as it was thought he was dying. After some hours of prostra-tion he rapidly recovered. I remember well also a case of fatal poisoning by arsenic where the vomiting, purging, and collapse were so great that it resembled closely a case of cholera, and I remarked at the time that any number of cases of poisoning by arsenic might occur during a cholera epidemic and not be detected. It may be observed that in the case reported in your journal it is said that the patient had the most violent cramps and to ease her the limbs were wrapped in warm flannels. certainly is not the best treatment, since cold applications are far the best. In the numerous cases I saw, the wrapping the legs round with bandages wrung out of ice-cold water gave the most relief; everyone knows the ready method of relieving cramp in the legs when it comes on at night in a warm bed is for the occupier to jump out of his bed and stand on the cold stone of the hearth, if there should be one in the room.

This first epidemic of cholera in England was in the year 1831, and of this I have some recollection myself, not, of course, of the disease, but only of its occurrence, as I was only about six or seven years of age. Next door to the house in which I lived a lady was taken ill after the departure of her husband to business and she sent in her servant to request my mother to go and see her. This my mother did, and on her return she related how the poor woman was lying quite prostrate in bed and at the same time the doctor who had been sent for came in. He went to the

bedside, felt her hand, and then walked as far off as he could, held a bottle to his nose, said he would send her some medicine, and then departed. This made a great impression upon me, especially when my father returned home from the East India House in the afternoon and this was all related again to him. His only expression was, "What an awful disease." She was well in the morning and dead at night!

The next epidemic, in the year 1848, I well remember, for it was in the summer of that year that I went to Paris with Dr. Habershon, who was afterwards my colleague, in order that we might visit the Paris hospitals. The cholera had just entered the city and then so rapidly spread that when we went to the Hôtel Dieu one morning we found 50 cases or more had come in since the day before; one of the physicians. whose name I forget, was going through all the remedies in the pharmacopæia by way of experiment, and I think on that day he was giving manganese. Our parents wrote requesting our return, which we complied with, but thinking it better not to stay in London, then rapidly becoming a prey to the epidemic, we took our holiday in Scotland. A few days afterwards my old master Aston Key, living in St. Helen'splace, in the City, died from cholera after two days' illness, in spite of the close attention of Addison and Gull. His death causing a vacancy and also various promotions, my friend Habershon obtained his first appointment at Guy's in the dissecting-room.

It was in the next epidemic, in the summer of 1854, that I obtained so large an experience of the disease. then living in St. Thomas-street, near the hospital, and there were two consulting physicians in the Borough—Dr. Barlow and Dr. Hughes. The former's private home was at Sydenham, where he retired in the evening, and he did not come to town on Sunday. His colleague declined to visit any case of cholera, so a large amount of consultation practice fell to me at a very early period of my practice, but I need scarcely add it sadly fell off again when the epidemic was over. At that time it was clearly made out that the infection or poisonous matter was introduced through the water, and this was contaminated by the excreta of cholera patients. The case of the Broad-street pump in Soho was a striking proof of it, since it was found that more than 200 people who came there for their drinking water had been attacked. So many other examples of the same kind occurred that there could be no longer any doubt that the polluted water contained the germ of the disease. At that time bacteria were unknown and the "comma bacillus" of Koch is comparatively a new discovery. Whether this is still credited with being the "fons et origo mali" I have no knowledge, having been so long out of the profession. When the word bacteria" was first used at the Pathological Society a well-known member asked, "What had frogs to do with the He was evidently thinking of "batrachia." disease?" As regards the future, we are in a far better position than in the times of the former epidemics, owing to our improved sanitary arrangements, for then the river Thames was the main sewer. I remember well when passing over London Bridge or Blackfriars Bridge the river literally stank. the same time many parts of the suburbs were supplied by the same river for culinary and drinking purposes. The water might have come from Kingston, above where the tidal flow ceased, and might afterwards have been filtered, but it ran a great risk of being polluted when its source was so small a distance above the commencement of the tidal flows. The value of the new sewer on both sides of the river may be seen in the apparently approaching epidemic of 1866, when after the occurrence of a few cases it ceased to spread and soon afterwards quite died out. We have not, therefore, much fear for the future. This last slight outbreak ought to be remembered in connexion with that remarkably clever and originally minded man, Sir John Simon. He had not been long in his public office when the opportunity occurred for making a thorough scientific investigation of the causes and treatment of cholera. He being in a public office considered that this should be undertaken by the Government. On its assent Sir John Simon proposed that a small committee of medical men should be appointed to determine the best method of investigation, and I have now before me a letter from the medical department of the Privy Council Office inviting me with others to attend the committee, at the same time stating how unsatisfactory our present knowledge was, both with regard to nature and treatment of cholera. The Lords of Her Majesty's Council therefore required the aid of the

best-informed members of the medical profession. mention of particulars required in connexion with the disease and amongst others "post-choleraic fever." This was certainly a remarkable phase in the disease, although its presence was exceptional, and it was accompanied by a rash; models of this eruption in wax are now to be seen in the museum of Guy's Hospital. It had been observed in more than one of the epidemics. regards the committee meeting at the Privy Council Office, Dr. Bristowe and myself were chosen to do the practical work—that is, to make a special study of the disease as regards causes, contagion, treatment, &c. Probably I might have been chosen because of my knowledge of post-mortem appearances, having made several examinations of the bodies after death. The appearances I have described in my work on "Pathological Anatomy," the most notable being that of the intestines, which instead of being distended with gas lay in a small compass, feeling sodden, doughy, and flabby. I should regard this remarkable appearance as quite distinctive and enough to prove its presence without any further examination. You will thus see that I have lived during all the occasions of the cholera's invasion of England.

Last, and not least, the document ends by saying: "My Lords propose to offer you a fee of £100 for the assistance requested of you." Such an offer is so unusual that it must have been at the instigation of Sir John Simon who considered that his medical brethren should not do work for I am, Sir, yours faithfully, SAMUEL WILKS. nothing.

Hampstead, Sept. 25th, 1909.

THE NATURE OF ANGINA PECTORIS.

To the Editor of THE LANCET.

SIR,-Dr. Beddard's letter in your issue of Sept. 18th on angina pectoris in cases of mitral disease-I will not limit it to mitral "stenosis"—is very interesting to me. I am not sure whether I have or have not mentioned these cases in print, but I think I referred to them in my Mount Vernon address. At Belfast the necessarily shorter time at my disposal determined me to omit them, lest I should, really or apparently, obscure the main principles of causation.

These mitral cases, if we exclude cases of mixed or dubious nature, are exceedingly rare; so few as to present inadequate data for argument. They are absolutely so rare that I have notes of but two cases only among my own observations (neither with necropsies), and I have not been able to collect any definite addition to them from published records; for, as I need not say, the diagnosis must be unequivocal. I have been surprised indeed to find even distinguished clinical observers using the name "angina pectoris" indiscriminately—e.g., for anxious cardiac oppressions, or for agonising paroxysms of dyspnœa, such as those of high blood pressure so admirably described afresh in a recent paper by Professor Pal, and so on.

Meanwhile, I think we must suspend our judgment about these notable cases, as being exceptional. In one of my cases, attended with sudden onset of mitral regurgitation, there was some reason to suspect a mixed causation. In the somewhat frequent syphilitic angina pectoris a double lesion may of course be suspected. I hope, with Dr. Beddard's assistance, to add to our evidence on this part of the subject. I am, Sir, yours faithfully,

Cambridge, Sept. 24th, 1909.

CLIFFORD ALLBUTT.

ABSCESS OF THE BRAIN IN ASSOCIATION WITH PULMONARY DISEASE.

To the Editor of THE LANCET.

SIR,-I have read with great interest the collection of cases in the late Dr. Schorstein's lecture on the connexion between pulmonary disease and cerebral abscess, the point which particularly interests me being the absence of tubercle ba illi in the pulmonary lesions. I venture to draw attention to the following case in connexion with the pulmonary, and possibly the cerebral, lesion in some of Dr. Schorstein's series :

X.Y. was sent to hospital in China in 1904 or 1905 for pulmonary tuberculosis. He had syphilis two years before, but only attended regularly for treatment three months. His preentillness started with symptoms of peripheral neuritis which

chest then became involved and he was sent to hospital. He had been in hospital some time when I saw him in consultation. He was thin and had an evening rise of temperature with incomplete morning remission. He spat up a good deal of muco-purulent sputum which was examined for tubercle bacilli several times with negative result. There were signs of fairly extensive consolidation and some cavity formation at the right base behind. The case looked like a tuberculous broncho-pneumonia which was going downhill.

The case was considered to be syphilitic because of (a) absence of tubercle bacilli in the sputum; (β) presence of signs of active syphilis on him-i.e., an ill-defined scattered rash, and coppery scars on the legs, for which he had had insufficient treatment; (γ) the lesion being at the base of the lung and the peripheral neuritis preceding it. The man was treated by mercurial inunctions, increasing doses of iodide of potassium, and anti-tuberculous hygiene and feeding. He got quite well and returned to his ship to duty, though there was, as would be expected, some diminished air entry at the right base behind.

The case struck me very much, as I had been looking for one for some time. I think they are likely to be more numerous ashore as the patient very often attends the doctor (not his family doctor) or the hospital for his original syphilis only as long as he has symptoms. Hence the predisposing cause, insufficient treatment. It would be of some interest if Wassermann's reaction and the effect of antisyphilitic treatment were tried in cases showing persistent absence of the tubercle bacilli from the sputum together with well-marked physical signs in the lungs. This could easily be done in an institution such as the Brompton Hospital. I believe I have seen other cases of the cannot recall them.—I am, Sir, yours faithfully,
L. LINDOP, believe I have seen other cases of this nature published, but

H.M.S. New Zealand, Home Fleet, Sept. 21st, 1909.

DOMICILIARY MEDICAL TREATMENT UNDER THE POOR-LAW.

To the Editor of THE LANCET.

SIR,-Considerations of space and some diffidence in criticising a man of Dr. Major Greenwood's experience and standing were the reasons for which I contented myself with uttering a protest against the sweeping affirmations made by him in his article in your issue of Sept. 4th. At the same time I did give two most cogent reasons against his opinion that practically the whole of the lower middle and working classes would be treated gratuitously if the recommendations of the "Minority Report" were adopted. If Dr. Major Greenwood will do me the honour to read my letter again, he will see that these reasons were: 1. That the duty of recovering the whole or part of the cost from those able to pay would be imposed on the authorities. Since at the present time nearly £300,000 annually are recovered by the authorities for the maintenance of children in industrial schools, of children in deaf-and-dumb schools, of inmates of asylums, and of paupers it is quite reasonable and probable to suppose that the same success would attend the above procedure. 2. That since those medically attended by the authorities would not be able to choose their own doctors, and since tastes differ, it is again reasonable to suppose that the whole of the lower middle class and the better off of the working class will still in the majority of cases seek a doctor of their own choosing. Surely these reasons are not mere negations. I am, Sir, yours faithfully,

London, W., Sept. 26th, 1909.

H. BECKETT-OVERY.

THE DIAGNOSIS OF FEVERS IN RANGOON.

To the Editor of THE LANCET.

SIR,-Permit me to correct a statement by Lieutepant-Colonel J. R. Forrest, R.A.M.C., in a paper he read before the Society of Tropical Medicine and Hygiene on July 16th, and published in THE LANCET on July 24th, p. 229. Lieutenant-Colonel Forrest is reported to have stated: "In Rangoon they had not yet emerged far from the period when every case of fever was returned under one of three headings," &c. Lieutenant-Colonel Forrest, R.A.M.O., sent illness started with symptoms of peripheral neuritis which headings," &c. Lientenant Colonel Forrest, R.A.M.C., cleared up under strychnine, massage, and electricity. His evidently only means by the term "they" officers

in charge of British troops or cantonments, as it is evident he obtained his experience only from this source. Inquiry by him, when he was in Burma, would have revealed the fact that for the past nine years to my knowledge fevers have been carefully investigated at the Civil General Hospital, Rangoon. Numerous papers on the subject of obscure fevers had been read at monthly meetings of the British Medical Association. I am also well aware that not only in Rangoon has the diagnosis of fevers been investigated by the aid of a clinical pathological department, and that considerable interest has been roused throughout the civil surgeoncies of this province for many years past. I therefore cannot allow Lieutenant-Colonel Forrest's reported misleading statement to pass, and can only conclude that he is referring only to the methods of station hospitals.—I am, Sir, yours faithfully,

E. R. Rost, Major, I.M.S. Rangoon, Sept. 4th, 1909.

THE EXHIBITION OF QUININE.

To the Editor of THE LANCET.

SIR,-A firm believer in quinine in the prophylaxis and treatment of malaria, I have been, as I suppose many others practising in the tropics have, surprised from time to time to see a man taken ill with malaria while using prophylactic

quinine or a pyrexia resist full doses of the drug.

Everyone in the tropics carries his own medicine chest, and in 99 per cent. of cases he has been prescribing for himself quinine in the form of tablets, often the sugar-coated variety, or some similar preparation, and herein lies the fault. When the gastro-intestinal catarrh commonly associated with malaria is taken into account, I have little hesitation in saying that the dose of quinine it is desired to bring into action in the blood bears often no relation to the number of tablets, for instance, swallowed. I am equally convinced that much of the "upsetting of the stomach complained of by persons taking quinine is due to the drug being taken in these forms. There can be no doubt that the only effective method of exhibiting quinine by mouth and that causing least ill-effects is as a solution. For this reason sugar-coated tablets should cease to appear on the market and only such salts of quinine as are easily soluble in water should be made up in these forms. Would it be too great an assumption of the rôle of the physician on the part of manufacturing chemists to give directions on the label that quinine tablets should be dissolved in water before being administered?

I am, Sir, yours faithfully, HUGH S. STANNUS, M.B. Lond.. Medical Officer, Nyasaland Administration.

DARK-GROUND ILLUMINATION FOR BACTERIOLOGICAL MICROSCOPY.

To the Editor of THE LANCET.

SIR,—Having read the interesting communications by Mr. H. Wansey Bayly and Mr. Shillington Scales in your issues of Sept. 11th, p. 782, and Sept. 18th, pp. 889-90, relative to the use of dark-ground illumination in the observation of living bacteria, &c., I should like to be allowed to add a few remarks. It is generally understood that the source of light required must be much more intense than is ordinarily used in microscopical work; in fact, the makers all recommend a strong light. At first I employed the small arc lamp made by Leitz in conjunction with his dark-ground condenser when searching for spirochætæ and bacilli, but found it advantageous to reduce the intensity of the light by interposing screens. Afterwards I discarded the arc lamp for the Nernst electric lamp, and eventually, for the incandescent gas lamp, the weaker light being more pleasant to the eyes and giving a better contrast between the brightly illuminated objects and the dark background. During the last few weeks I have been using the recently improved reflecting condenser by Leitz, which absorbs less light than his first model, and in consequence I have reduced the strength of my light to the ordinary microscope oil lamp with simple bull's eye lens, and the results are certainly surprising. Spirochætæ and typhoid bacilli, for example, are distinctly shown against a perfectly black background, and the light being less injurious to the eyes I was able to work continuously for several hours without feeling the usual fatigue which follows the use of strong illuminants.

The fact that so weak a light as an oil lamp can be used satisfactorily in this mode of illumination may not be so highly appreciated by those at home as workers abroad, especially in regions where such commodities as gas and electricity are not to be found. Several workers in tropical medicine whom I have met were obliged to give up the idea of adopting this mode of illumination because of the impossibility of getting a sufficiently strong source of light.

I am, Sir, your faithfully, Crouch Bnd, N., Sept. 20th, 1909. J. W. OGILVY, F.R.M.S.

DIAGNOSIS IN THE GYMNASIUM.

To the Editor of THE LANCET.

SIR,—This morning I was consulted by a young lady with lateral curvature of the spine: she had previously been advised by her family medical man to put herself under Sandow's treatment; so she was examined by Sandow who promised to cure her for 80 guineas. The parents could not afford this amount, so they decided to consult me.

Yesterday a father and mother brought me three sons who had recently been examined by Sandow; the latter said that one had serious disease of the spine and another serious heart

disease without any ground for such diagnoses.

You must agree with me that it is bad enough to see Sandow's costly advertisements in the daily press, but it is worse when general practitioners stultify themselves by sending their patients direct to him.

I am, Sir, yours faithfully, BERNARD ROTH. Harley-street, W., Sept. 24th, 1909.

THE HYPNOTIC TREATMENT OF MORPHINISM.

To the Editor of THE LANCET.

SIR,—The problems considered by the recent International Congress on Alcoholism in London are of world-wide importance, and the British Government showed a far-seeing comprehension of the needs of the times by inviting the principal Governments of Europe and America to send to this Congress their official representatives. Nothing but good can come from such a convention in which are assembled the most distinguished scholars and ablest specialists from the foremost nations of the world.

Among the drugs that enslave, the two with which the physicians of the United States are especially concerned are alcohol and morphine. While alcoholic intoxication is an ancient and well-understood condition, morphinism is a modern disease and has not received the attention from the medical profession which it deserves. It was almost unknown in the United States before the invention of the hypodermic syringe about 50 years ago, but now it has spread through that and other nations till it has become a world-wide menace to mankind. Unlike alcoholism, morphinism is not a social vice. It flourishes alone and in the dark. Unsuspected by the victim and unknown to his friends morphine quietly and insidiously becomes master and owner of the patient's brain and nerves, and steadily month by month drags him down to mental incapacity and to physical ruin. From first to last the victim of morphinism is in perpetual slavery. He does not have a day or a week of bondage, followed by a period of freedom, as is usually the case with alcoholics. Every day in the week and every week in the year the morphine yoke bears heavily upon him and escape is impossible without medical aid. As physicians well know, morphine cannot be denied an addict for 24 hours without causing great suffering, and after 48 hours of abstinence the agony is beyond the power of human nature voluntarily to endure. Neither is harmless moderation possible. If this drug is used daily, even in very small doses, the patient soon becomes a helpless slave to it. Morphinism is not a mere habit, but is a serious pathological condition. The will cannot be invoked for its cure as it is a disease in which the will is not a factor. It is as absurd to ask an addict to stop the use of morphine as to ask him to amputate his own arm. He can be cured only by a thorough course of sanatorium treatment. All other methods are a delusion and a snare.

The morphine addict could easily be cured, in fact, he could cure himself if it were not for the extreme suffering caused by depriving him of the drug. These withdrawal pains are so great that he is naturally willing to resort to the

most desperate means to obtain the drug which he knows will give him prompt and sure relief. Thus it becomes evident that all possibility of self-help is out of the question. Fear that he will suffer in the same way if he goes to an institution for treatment deters him from seeking remedial aid. How to cure these patients without suffering is, therefore, the most important factor in the problem. generally been considered impossible. I am convinced by years of experience in a sanatorium devoted to this specialty, that morphine can never be eliminated from an addict without suffering, if he is conscious, any more than his hand could be amputated without pain under similar circumstances. I therefore lay down the general principle that sleep solves the problem of the painless withdrawal of morphine as it has solved the problem of painless surgery. I have described this method of treating morphinism in other published papers. Briefly, it consists in keeping the patient asleep or in a somnolent state for a short time by the use of some of the hypnotic remedies that are familiar to all physicians. While the patient is thus somnolent the morphine is withdrawn. When he awakes the painful period is passed and all desire for morphine is gone. He then begins again to see clearly and to think normally. His outlook on life has entirely changed. Like John on Patmos, he beholds "a new heaven and a new earth." He begins once more to really live. While all this has been accomplished the patient has not suffered one minute of pain. The principle is the same as the administration of anæsthetics to obliterate the pain of a surgical operation. In carrying out this plan of treatment the physician's armamentarium should contain most of the hypnotic remedies, as no one remedy is sufficient. Among these hyoscine has been recommended, but I do not approve of it. It is a very uncertain, if not a dangerous, drug. For ten years I have been continuously using apomorphine in my sanatorium work for hypnotic purposes, and have found that in promptness and certainty of action it has no equal. While there are few infallible remedies, and this one may occasionally fail, yet among the hypnotics I know of none that is so certain in its effects. Its safety is another advantage. As one-tenth of a grain is universally considered a safe emetic dose, the hypnotic dose of one-thirtieth of a grain must be absolutely devoid of danger. The old gradual reduction method consists in reducing the size of the morphine dose daily till zero is reached. This means long-drawn-out misery for the patient as well as uncertain results. On the other hand, the method herein described is not only painless but sure. The after-treatment of morphinism is very important and should last several weeks. In addition to the products of the Pharmacopeia I find high-frequency electricity, mechanical vibration, light therapy, &c., often of great value during this period.

To the resolution of the International Conference at Shanghai last February asking for international investigation regarding methods of treatment for the opium habit, I would make this reply: Morphinism can be cured surely, safely, and painlessly by a method that has been repeatedly used with all classes of patients under careful scientific observation. This method consists in artificially inducing the somnolent state during the withdrawal period.

I am, Sir, yours faithfully,

C. J. DOUGLAS, M.D.

The Douglas Sanatorium, Dorchester, Mass., U.S.A., Sept. 20th, 1909

RAT DESTRUCTION ON SHIPS.

To the Editor of THE LANCET.

SIR,—My attention has been called to the report in your issue of the 18th inst. on the Sixteenth International Medical Congress at Budapest in which, on p. 875, Dr. Belleli is reported to have said in the course of a discussion on the different methods employed for the destruction of rats in ships that "the Clayton gases damage several kinds of goods; silks are discoloured by it, tea loses its aroma, and cargoes of silk and tea are constantly arriving from the Far East, representing an enormous total value." Of course, you give only a short summary of Dr. Belleli's remarks, but if Dr. Belleli declared without qualification that silks are discoloured and that tea loses its aroma when exposed to the action of the gas produced by my machine during the process of rat destruction on board ship, I can only say that he is very much misinformed. Numbers of vessels under all flags

have had their rats destroyed with silk and tea in their holds without any damage whatever resulting to these goods. The silks, of course, are in bales, thoroughly protected by careful wrapping; the tea is in chests lined with tin-foil. It is very doubtful whether the gas penetrates the bales of silks, and still more questionable whether it passes through the tin-foil protecting the tea. But, in any case, the fact remains that no damage has ever resulted to such goods, and this can be attested by numerous firms in London and elsewhere who have had practical experience in the matter.

I am at Dr. Belleli's disposal to furnish him proofs of what I state and to give him facilities to carry out any experiments he desires, and I trust that you will give to this letter the same publicity as you have given to your correspondent's résumé of Dr. Belleli's remarks.

I am, Sir, yours faithfully,

Paris, Sept. 22nd, 1909.

T. A. CLAYTON.

THE RECENT NAVAL COURT-MARTIAL.

To the Editor of THE LANCET.

SIR,-All naval medical officers will approve of your note on the foolish proceedings taken at a court-martial against Fleet-Surgeon C. G. Matthew, but such a situation as is described should be impossible. It clearly resulted from the want of definite assignment of rank in the titles of naval medical officers. The commander could not have behaved so petulantly towards an officer whose rank was the equal of his own if that rank had been quite clearly marked in the title by which the fleet-surgeon was addressed. The title "Fleet-Surgeon" merely indicated to the commander an officer of seniority but of a subordinated branch. The title "Commander" would mark a man as an officer whom by instinct another commander would deal with as an equal. In the army the commander in this case would at his age have probably been a major and the fleet-surgeon a lieutenantcolonel, when such abuse of authority could never have occurred. If the Admiralty desire to prevent such occurrences in future they will attend to this lesson of the case. If rank, however, cannot be given, pay can, and increased pay generally secures increased consideration. If the Admiralty Committee on the Naval Medical Department cannot recommend more definite titular rank it should recommend material increase of pay to compensate for the obvious hardships which this case shows may lie before professional men who join the navy rather than the other military services of the State.

I am, Sir, yours faithfully.

Sept. 25th, 1909.

A. B. C.

** We doubt the value of our correspondent's proposal to obviate such occurrences by titular alterations.—Ed. L.

NURSING IN MONTGOMERYSHIRE.—A scheme for the formation of a County Nursing Association was discussed at a largely attended meeting held at the Victoria Hall, Newton, Montgomeryshire, on Sept. 14th. Mr. David Davies, M.P., presided, and in his opening remarks pointed out that at the present moment no provision existed for nurses in rural districts in the county. Nursing associations had been formed, he believed, in connexion with every county in England. Wales, however, was very backward with regard to provision for nurses. Mr. C. E. Humphreys, medical officer for the county, said that the ideal nurse that was required for rural districts was a combination of district nurse and maternity nurse. county nursing association ought to be able to supervise its nurses in the same way that midwives were supervised. With regard to the training of nurses, they should not go through a three years' course but a 10 or 12 months' course—four as maternity nurses and eight as district nurses. They would also act as health visitors to teach poor women the best way to feed and care for the children. The establishment of such a system of nursing throughout the country would have a great effect in diminishing the infantile mortality which at present stood very high. The Montgomery County Nursing Association was subsequently constituted, Mrs. Edward Davies being appointed president. The executive committee, consisting of 18 members, includes the names of Dr. Rees, Mr. W. E. L. Davies, Mr. R. D. Thomas, and Mr. N. W.

THE TERRITORIAL MEDICAL SERVICE. (FROM A SPECIAL CORRESPONDENT.)

VI.—THE MEDICAL ASPECT OF THE FOOD-SUPPLY OF THE SOLDIER.

A PROPER food-supply is absolutely necessary for health, vigour, and energy during the performance of military duties and too much attention cannot be paid to the arrangement of a proper dietary and its culinary preparations. The rations of the soldier are at all times a matter of great importance, but in war the success of a campaign depends materially on them. If food-supplies fail or are scanty on active service debility will ensue; debility leads to disease, and disease to disaster in military operations. The lack of suitable food broke the back of Napoleon's great army in Poland in 1806, and again led to his disastrous retreat from Moscow in 1812, in which he lost 400,000 men. Want of sufficient food led to our retreat to Corunna; it also caused disasters in the Orimea and in many other campaigns which furnish a list too lengthy to mention. Parkes, one of our greatest military medical authorities on food-supplies in war, writing on their failure, states: "The effect of food upon strength, endurance, and even courage is remarkable. It is useless to supply the ammunition for guns if the men who have to work them have no supply of energy issued also to them." General Sherman says the four most important duties of the commander of an army should be the proper supply of food to his soldiers, of suitable clothing according to climate, of shelter from the weather, and of prompt medical assistance to the sick and wounded. These are four duties a commander should never neglect personally to attend to, for who, after all, should take so much interest in the welfare of the soldier as their general, who owes them a lasting debt of gratitude for his fame, towards the attainment of which they so largely contribute. In the army every officer, from the general in supreme command to the last omeer, from the general in supreme command to the last joined subaltern, must give the subject of rations and the feeding of their men the closest personal attention, for the troops in this matter depend entirely on their officers. Once the troops are satisfied that their superiors are doing their best in this respect they will not "grouse," and will bear cheerfully the most severe privations. So much depends on food, especially in war, that the soldier should have the best in the market, and there should be no "cheeseparing" policy, so long as economy of transport is not interfered

Modern physiological research proves that the composition of foodstuffs is most complex and that besides calculating their energy value it is also necessary to consider their chemical composition and the questions of personal likes and dislikes of the consumers. Rations that are unpalatable and consumed without relish by troops cannot in all cases be regarded as physiologically beneficial, and general health may suffer. A dietary loses its value if it is very monotonous, and it has been held, imaginative though it may seem, that on active service this monotony makes troops liable to scurvy. The causes of scorbutic conditions met with on field service are as yet imperfectly understood, and while in some cases they have been attributed to the use of tinned meats and preserved vegetables, the writer has noticed many of the signs and symptoms of scorbutic affections appear not only in troops on service but also amongst others in civil life at home and abroad amongst whom fresh meat and fresh vegetables were their daily diet, but where the necessary variations in diet were not employed; and he is forced to conclude that a "sameness of diet" or, so to speak, a want of variation may be considered the causal factor. The recruit usually will require more food than the fully trained soldier, as the majority of the newly joined soldiers are growing lads and were perhaps out of employment and badly fed before enlistment. The main factors determining the amount of food necessary for the soldier must be the amount of physical work he has to do and the amount of muscular energy necessary to perform this. The harder the work the more the amount of food required, and with strenuous exertions an average of more than 4000. Calories must be provided if his strength and military

efficiency are to be maintained. The popular idea that the Japanese army in the Russo-Japanese war consumed very little food is erroneous, as their war ration was considerably higher in energy value than that of our own army during the South African war, although the ration of the latter represented a fairly reasonable basis. During war the troops have to depend to a large extent upon preserved rations, notably tinned meat; the palatability and quality of the various brands of the latter are subject to great variations.

In the report upon the food of the soldier,2 recently issued by the subcommittee of the Advisory Board to the Medical Services appointed by the War Office, many important suggestions have been made as a result of its investigations. In regard to the amount of fat in tinned meat the subcommittee considers that meat with less than 10 per cent. or more than 15 per cent. of fat is unpalatable to most men. It also considers that the reason why tins of meat after passing the tests applied by the manufacturers become suddenly blown after keeping good for months or maybe years, a condition thought to be due to minute punctures occurring from rust or damage allowing air to enter, is really that development occurs of spores of bacilli, such as the bacillus cadaveris, which were present in the meat at the time of packing and were not destroyed by sterilisation, the heat of sterilisation having been insufficient to penetrate to the central parts of the meat in the tin. In some cases the amount of nitrate derived from the pickling fluid was found excessive, and its ingestion would probably cause gastric derangement. The nature of "can-burn" was found to be due to a deposit of sulphide of tin, sulphide of iron, and oleate of iron. The subcommittee came to the following sound and practical conclusions: (1) That the soldier, both the recruit and the trained soldier, receives sufficient food during peace time and that its quality and variety are generally satisfactory; (2) that further investigations concerning the field service rations are needed; (3) that the supply of tinned meat requires careful supervision, for some brands contained meats of inferior quality; (4) that to prevent "blowing" of tins the lowest temperature of the surrounding sterilising fluid during manufacture which will completely sterilise the tins within a reasonable time is 120° C. (248° F.), and that this temperature must act for not less than 60 minutes; and (5) that the amount of fat in tinned meat should be from 10 to 15 per cent. It was recommended that the preparation of tinned meats should continue to receive, as at present, the careful supervision of the supply branch of the army, and that there should be a definite relation between the weight of a tin and its contents. The tins should be painted and not lacquered, and no paper labels should be used (these cause perforation by becoming damp and corrosion by rust); all tins to have their date of issue embossed on the tin; sample tins to be examined after incubation for a fortnight at 37° C.

Next to having a proper food-supply for troops is the importance of its preparation. Too much attention cannot be paid to good cooking, and Territorial soldiers, like the regular army, should be trained individually to be able to cook for themselves while in camp, as in war time it often occurs that a man may have to cook his own rations. The want of knowledge in elementary cooking amongst men generally is appalling. Even in the regular army in the early days of the South African war the writer frequently came across officers and men who could neither light a fire in the open nor cook food, nor in some cases even make their own tea.

Soldiers seldom complain on service of their rations, they accept the inevitable, and for this reason the greatest supervision ought to be exercised by all officers, not only over the supplies they receive, but also over the methods of preparation, cooking, and service in the field. Troops consider it unsoldierlike to complain on service unless things are very bad; as a rule they content themselves and have a strong pride about roughing it, a pride almost professional, which hinders them making any complaint. The subject of cooking in the army is one that has occupied the War Office authorities much of late, and it is one of considerable importance. In India General Burnett, when commanding the Poona Division, started a school of cookery in which selected men from all regiments now undergo courses of instruction. Such instruction is greatly appreciated, and its

¹ Nos. I., II., IV., and V. were published in The LANCET of July 31st, August 7th, 14th, and 21st, and Sept. 25th, 1909, respectively.

² See THE LARCET, July 17th, 1909, p. 157.

provision should be encouraged in every possible way. To cook well and rapidly is an art which can be easily acquired, and which every officer and man should learn. It is also desirable in peace time that men should be in-structed in the slaughtering of cattle, the cutting up and issuing of meat, and the construction of field kitchens. A roster should be kept regimentally of the names of all men so instructed, and each man should be marked off and his name registered when passed as efficient. This system was introduced in India by Lord Kitchener, and it has proved most successful. During recent years the question of supplying troops on active service with food cooked in travelling kitchens has engaged the attention of the continental powers as well as our own War Office. In order to obtain a field kitchen of a transportable nature suitable for the German army the German Ministry for War offered a prize open to a public competition in 1905 and 1906. The special conditions laid down as necessary were that the field kitchen should be constructed as a two-horse four-wheeled vehicle, the hind carriage to be easily detachable from the front part of the car, and each section to be capable of being drawn by one horse and used independently if necessary. The kitchen must be able to follow infantry along roads at a trot and also to be capable of transit over soft or uneven ground. The hind car must carry the kitchen utensils, extra rations for the horses, fuel for one day, drivers' baggage, and 200 extra rations for the troops in a separate compartment. The total weight of the loaded vehicle, exclusive of the drivers, must not exceed 1100 kilogrammes. All varieties of rations were to be cooked, and special arrangements were to be employed to prevent the danger of burning the food by the use of a bath of glycerine. As a result of the trials a field kitchen was finally selected comprising a copper holding 200 litres in a boiling bath, and a boiler holding 70 litres of water for making tea or coffee; both these boilers may be heated either singly or together. The boiling bath surrounds the whole of the inner copper and prevents the food being burned. The fuel used may be either coal, wood, or peat, and after 12 hours the temperature of the food still has a warmth of 140° F., and was palatable up to 72 hours When the food is being served out, or when the kitchen is being cleaned, the fore part of the vehicle may be sent away for a fresh supply of food. It has since been decided to supply a complete travelling kitchen to each company of infantry, battery of artillery, The troops will, however, still carry their mess tins and be trained to cook for themselves. The wheeled kitchens are filled up from the company supply wagons, which carry one day's rations, three tea rations per man, and one day's rations for each riding horse, besides butcher's utensils, each company having its own skilled butcher. The company supply carts are filled from the supply columns and other central stores, or else by local purchase. Another cart for supply purposes acting as a canteen where the troops can purchase food, is also allotted to each battalion. During the German military manœuvres at Jauer and Seignitz in August, 1908, at the midday halt, cattle were slaughtered on the spot and cut up and cooked for two battalions of infantry; each company prepared their dinners differently, using only their mess tins and making fires of wood carried by themselves. Another pattern of travelling kitchen acts as a steamer, the central boiler having steam passed through it. Ten camp kettles, each containing rations for 12 men, are put in the steamer before marching, and on arrival at the midday halt they contain a savoury stew. Much time is thus saved from not having to cook food on arrival. Digester boilers have also been tried in which the food is rapidly cooked under high-steam pressure which reduces the toughest meat to tenderness. Another pattern is the Swedish feltcovered boiler which keeps food warm for a considerable time. At the Austrian manœuvres of 1908 Daimler motor kitchens were tried with considerable success; these appear more adaptable for battalion cooking than for company work. Another great advantage is that they can be rapidly moved from the rear to the front and they supply cooked food when the troops halt at midday. Our own War Office is at present making trials of a travelling kitchen at manœuvres.

I will conclude the consideration of the important subject of the food-supply of the soldier on active service with a few general remarks, for the elementary nature of which I must applopise to readers of THE LANCET. Men's rations should be most other counties as well.

varied from day to day as far as possible, and no opportunity should be lost of obtaining fresh green vegetables. Lord Wolseley has suggested that mustard and cress seed might be sent on field service, and the idea is certainly a novel one that might be usefully employed on the lines of communication or in blockhouse gardens, as all green vegetables are good anti-scorbutics. Officers and men should always have something to eat and drink before they commence a day's work, no matter how little and no matter how early. A cup of hot tea, coffee, or cocoa and a few biscuits will suffice for an early morning meal before a regular breakfast. The regulations state that "regimental arrangements should be made for a cup of hot coffee to be provided at night for every sentry on guard"; this is an important order and medical officers should inquire concerning its being carried out. All officers should be sufficiently interested in the welfare of their men to look after their rations, and if they find them insufficient or of bad quality they should report the fact at once; they should also see that their men get hot meals as often as possible, but more especially are these valuable after a long march or a hard day's fighting. When men are employed on patrols, picquets, or any kind of outpost duty it should be ascertained that their rations are sufficient for at least 24 hours (cooked if necessary), and that water-bottles have been filled before starting. If an advance guard of a force is much harassed during the day they should not be employed for outpost or other duty during the night; fresh troops should be sent out if mili-tary exigencies allow. This will allow the advance guard to have their food and rest in comfort.

One of the most important considerations on service is that of transport for rations. The average weight of a man's ration is 3 to 4 pounds, and it cannot be reduced with safety below 3½ pounds. In times of emergency the soldier can carry four or five days' supplies if put to it, but in hilly countries, where it is essential that European troops should be burdened as little as possible, they should as a rule only be made to carry one day's supplies. The reserve supplies must be carried either on transport wagons in the case of flat country or where there are roads, or on pack mules in the case of hilly countries; the latter can generally travel anywhere that infantry can go. Men should always start a day's march with biscuits, emergency ration, and either preserved meat or cooked fresh meat in their mess tins.

A great deal of what has been written in this series of articles must have been very well known to medical readers, but the intention was to bring to the notice of the medical officers of the Territorial Service as far as possible all the points where their practical knowledge would be required, and the carrying out of this intention made the inclusion of certain elementary information necessary.

Pediculosis in Devonshire.—We learn from the Exeter Gazette that the prevention of pediculosis amongst school children occupied the attention of the Devon county council on Sept. 24th. The education committee had recommended the appointment of three special nurses at a salary not exceeding £80 for one year to work under the direction of the county medical officer and deal with the disease thoroughly. Sir Thomas Acland moved the adoption of the report on the grounds that the school inspectors' letters of admonition to the parents of infected children had failed to produce any improvement, a statement that was contradicted. Other members objected on the score of expense to the ratepayers, and an amendment was moved to the effect that the matter stand over until the report on medical inspection of schools had been received. In the debate that followed it was stated that 50 per cent. of the council's school children were infected with lice. The chairman, Earl Fortescue, put the number down at "something like 10,000 unfortunate little girls," but he considered that the necessary cleansing could be done by district nurses and others, and he supported the amendment, which was carried by a large majority, although Sir Thomas Acland pleaded for the adoption of the report on behalf of the children at present uninfected and their parents. It is obvious that a liberal use of the scissors is desirable in the elementary girls' schools of Devon, and for that matter in

THE

NINTH INTERNATIONAL VETERINARY CONGRESS AT THE HAGUE, SEPT. 14th to 19th.

(FROM A SPECIAL CORRESPONDENT.)

AMONGST the numerous subjects set down for discussion in the programme of the recent International Veterinary Congress it is not surprising that tuberculosis occupied a prominent position.

Governmental Efforts against Tuberoulosis, with Regard to the Ways of Infection in this Disease,

was the title under which the main issue was discussed, although several papers of general interest were presented under sectional headings.

Dr. BANG (Copenhagen), dealing with his subject at great length, stated that tuberculosis may be spread amongst calves and pigs by the milk they drink, and especially by the milk products returned from the cooperating dairies. legal provisions existing in Denmark since 1898 to avert this danger enforce the heating of skimmed milk, butter milk, &c., in the dairies to 80° C., and supervision of the execution of these provisions. He does not, however, think this control satisfactory, as it is not frequently enough practised, and he intimates that the best control might be obtained by choosing among the farmers in every dairy district a member upon whom the task would be incumbent of examining the milk every day according to Storch's method. Notwithstanding the unsatisfactory supervision, the Danish provisions have rendered invaluable prophylactic services against the spread of tuberculosis, and Dr. Bang urgently recommends the in-troduction of similar provisions into all those countries where the skimmed milk, &c., from the dairies is returned to the purveyors.

Professor Dewar (Edinburgh) regretted that, although an animal may be condemned as a milk-producer, the law does not give power to seize and destroy her. She can be turned out of the dairy byre, but she may be sold into some adjacent district in which inspection is lax or non-existent and continue to communicate tuberculosis to those consuming her milk. In considering the problem of the suppression or eradication of tuberculosis it is at once evident that it may be looked at from two very different standpoints—from the public health point of view, mostly as it affects meat and milk and the manner in which these may communicate the disease to human beings; and from the veterinary and agricultural point of view, by taking account only of how the disease is propagated and disseminated amongst animals and the losses it causes amongst our heards.

Dr. J. Poels (Rotterdam) said that the breeding of calves free from tuberculosis should be promoted and the eximmed milk should only be delivered pasteurised. In every country a central governmental laboratory should be established where morbid material and milk could be examined bacteriologically for the assistance of veterinary surgeons and proprietors of cattle in discovering the animals suffering from tuberculosis. Dr. Poels suggested the forming of an International Tuberculosis Committee for the purpose of fighting tuberculosis in cattle. He continued: "From the German statistics it appears that the number of deaths from tuberculosis in mankind diminishes, whereas the tuberculosis in cattle and pigs increases in many countries in an alarming degree. The fighting of tuberculosis amongst human beings will in the near future not be dependent on individual ideas but it will be considered a general public necessity and take rapid strides forward, and the expenses incurred for this work will be paid reluctantly at the commencement but finally with eagerness by the different states. Why has so little been done to fight against cattle tuberculosis, whereas almost every country takes or has taken strong measures against other conbagious cattle diseases? The answer will be that it costs too much. This, however, cannot be given as a reason, as the damage caused by tuberculosis is so large that the Government are no longer justified in hesitating to act on the score of expense. If the Governments are unable or unwilling to bear these expenses then they should be met by the establishment of a State fund, which can be supported by introducing a

poll-tax charged so much per cow. The idea that tuberculosis can be quickly overcome is prejudicial to the keeping up of measures to fight this disease. This idea is quite false, for many years must elapse before a marked improvement can many years must elapse before a market improvement can take place, so that posterity will profit by the fruits of our endeavours more than we. Now comes the difficult question, How have the Governments to fight? Veterinarians are split up into two parties. The one party wishes to follow Dr. Bang's suggestion—i.e., that cattle on all farms should be tested by competent veterinarians with the tuberculin test, and the herd then divided into two portions, tuberculous and non-tuberculous. Of the former those with clinical signs of tuberculosis should be slaughtered, the remainder being allowed to live out the ordinary course of their lives, all their milk being boiled before being used for food of man or animal, and any calves they produce must be immediately placed among the non-infected portion of the herd, as it has been found that it is only an almost negligible proportion of calves which are tuberculous at birth. The other party is desirous of following Ostertag (Germany) who suggests even more drastic measures." Dr. Poels concluded with an eloquent appeal to the Congress inviting the members to make attempts for promoting more harmony than has been shown in the past. "I will ask," he said, "in what way can the Congress be of service in bringing about the necessary unity? According to my idea this may be attained by establishing an international committee to fight against tuberculosis; this tuberculosis committee to work at the International Veterinary Congress and assemble once a year for the purpose of bringing a complete report of its efforts to each congress. The committee to be, therefore, a subdivision of the Congress. I suggest that this Congress appoint such a committee at once.

Vaccination Against Tuberculosis

was the subject discussed by Dr. EBER (Germany), Dr. HEYMANS (Belgium), Dr. KLIMNER (Germany), Dr. STRUTZ (Germany), and M. H. VALLÉE (France). The method of vaccination recommended is the introduction of non-attenuated tuberculous bacilli enclosed in a dialysing membrane, which permits the endosmosis of the nutritive substances of the organism and the exosmosis of the products from bacillary activity. As a dialysing membrane the most appropriate is the endodermis of a reed used simply or reinforced by a thin layer of collodion. Such bags placed in a glycerinated bouillon allow the bacilli that they contain to multiply and render it rich in tuberculin. These little bags containing bacilli, hermetically closed and placed in a gelatin capsule, make a vaccine which can be used without danger and can be easily employed on bovines. Inserted under the skin behind the shoulder with a trocar, the vaccine becomes encysted and forms a vaccinatory tubercle. With the exception of Dr. Heymans the speakers were of the opinion that up to the present the results have been unsatisfactory and that the immunity of animals has not been yet procured by this method of treatment. Several members of the Congress availed themselves of the opportunity afforded them of a visit to the State Veterinary Bacteriological Institute at Rotterdam, where several sera not yet in use in this country are produced. They have here a serum used in connexion with tuberculosis, but the results so far have not been very successful, although, on the other hand, mammitis and mastitis are successfully dealt with.

The Transmission of Avian Tuberoulosis to Mammals.

Under this heading Dr. ARLOING (Lyons), Dr. G. MOHLER (Washington), and Dr. BANG contributed convincing papers on the relationship of the organisms. These three observers were unanimous in their conclusions that avian tuberculosis is not a special disease caused by a special bacillus but a modified form of the bacillus described by Koch as the infective agent in human tuberculosis, with which it appears the avian bacillus is connected by common primary characters and from which it can be distinguished by secondary and, moreover, inconstant properties. Dr. Mohler maintained that the ravages of tuberculosis in the avian family are so patent that the gravity and increasing prevalence of this affection must not be ignored. The outbreak of fowl tuberculosis in the United States was not reported until 1900, when it was observed in Oregon; since then the disease has been located in California, New York, Michigan, and Canada. In the cases investigated by the Pathological Division of the American Bureau of Animal Industry both

dead and live birds were received showing both incipient and generalised tuberculosis as attested by microscopic demonstration of the tubercle bacillus and the feeding experi-ments which resulted successfully in from three to five months. The importance of continued investigation along this line is shown by the fact that numerous vague diagnoses under the title of liver disease, spotted liver, rheumatism, &c., are common amongst people interested in poultry. Some of these disorders have been proved to be tuberculosis, which suggests that avian tuberculosis is rapidly becoming disseminated. The finding by all investigators of multitudes of tubercle bacilli in the fæces suggests the ease with which the disease may be spread throughout the flock. Dr. Mohler mentioned an interesting case in which some chickens were affected with tuberculosis and after death their carcasses were eaten by pigs on the same farm which in turn developed tuberculosis. In order more definitely to connect the two cases a pig proved by the tuberculin test to be free from the complaint was fed upon the carcass of one of these birds, and when killed at the end of 104 days the pig was found to be tuberculous. Another interesting case concerned an egg laid by a tuberculous hen. It was carefully opened aseptically at the larger end and numerous smears were made of its contents. No tubercle bacilli could be determined by these means, so recourse was had to guinea-pig inoculation. The syringe was carefully filled with white of the egg without disturbing the yelk, and two guinea-pigs were at once inoculated intra-abdominally. Following this the process was repeated on other guinea-pigs using the yelk as material for injection. 36 days after these inoculations one of the guinea-pigs that had received a portion of the white of the egg died. On examination a degenerated area some 5 by 20 millimetres was found between the muscular layers of the abdominal walls. This area appeared inflamed and contained numerous small yellowish-white foci in which on microscopical examination numerous tubercle bacilli were found. The spleen of this guinea-pig was enlarged to fully three times its natural size and was considerably darkened in its colour. No tuberculous foci were visible in this organ, but the presence of tubercle bacilli was readily demonstrated by means of smears. The carcass of the guinea-pig was in excellent condition, showing no emaciation. The other guinea-pig, which received an inoculation with white of egg, died on the forty-third day, and although no tuberculous foci were determined, the spleen and the mesenteric glands contained such numbers of tubercle bacilli as to produce well-marked lesions in guinea-pigs sub-inoculated with them. From these lesions typical avian cultures were recovered upon egg media. The guinea-pigs receiving yelk inoculations failed to develop tuberculosis after observation for 68 days followed by necropsy. With these facts established the following conclusions were arrived at. Eggs produced by tuberculous fowls should be considered dangerous until cooked as they may harbour tubercle bacilli in important numbers. Tubercle bacilli of one species may be transmitted to an animal of a different species, which fact makes it apparent that any preventive methods for controlling tuberculosis to be successful must take into consideration all species of animals that are susceptible to tuberculosis.

Dr. L. DE BLIECK (Dutch East Indies) Mr. J. LIGNIÈRES (Argentine), M. L. PANISSET (France), Dr. J. SCHNÜRER (Austria), Dr. A. WLADIMIROFF (Russia), and Dr. SCHÜTZ (Germany) presented reports on

The Diagnosis of Infectious Diseases by Means of the Recently Discovered Reactions of Immunity.

Notwithstanding that the subcutaneons injection of tuberculin and mallein were excepted from these papers the majority of the reporters confined their discourse to these two tests. Dr. DE BLIECK dealt with the application made in veterinary medicine of the reactions of immunity to reveal contagious diseases, either agglutination, fixation with alexin, cutaneous and ophthalmic reactions of tuberculin and of mallein. From these papers the following conclusions were drawn: (1) reactions of immunity are of great value for the diagnosis of infectious diseases; (2) the comparative study of the various reactions, especially of the cutaneous and the ophthalmic, with a view to their extended employment, was recommended by the Congress; (3) the ophthalmic reaction is specific for distemper, and sero-diagnosis deserves to be tested further; and (4) these methods, wherever it is possible, should be employed in conjunction, but serodiagnosis should be done only in central laboratories.

Tropical Diseases of Animals formed the fifth section of the programme. Under this heading

Teaching and Laboratories for Research in Tropical Diseases received the attention of Dr. DE BLIECK, Dr. J. DE DOES (Netherlands). Dr. P. KNUTH (Germany), and M. H. VALLEB (France), who were all of opinion that it was of the greatest importance that those countries having colonies in the tropical or sub-tropical regions should institute special schools for the training of such veterinary surgeons as they may require to practise in those colonies. It is also necessary when training veterinary surgeons destined for the colonies to prepare them as thoroughly as possible, not only with regard to veterinary science, but also with regard to agricultural economy. The fact should never be lost sight of that colonial veterinary surgeons will be called upon to assist the labours of merchants and farmers, and in every respect much must be required from them in the future. It is therefore the duty of the authorities to secure for them a good social and pecuniary position, in order that a staff of veterinary surgeons may be formed as soon as possible, who will, so to speak, regard the colony as their second native country. It is satisfactory to note that our newest colony-i.e., the Transvaal—is the proud possessor of the newest and most perfectly equipped bacteriological laboratories yet erected in any colony.

Hygiene in the Maritime Transport of Cattle

was a subject which elicited papers by Mayor HOOGKAMER (Netherlands) and Mr. RICKMANN (Germany), who proposed a code of rules regulating the sanitary conditions to be observed in the transport of cattle and skins, advocating thorough disinfection.

The Prophylaxis and Pathology of Protocoan Diseases.

This topic was introduced by Dr. Knuth (Germany) and led to a discussion in which the following conclusions were enunciated concerning the prophylactic measures to be taken against protozoan diseases. In the present state of scientific knowledge the chief safeguard against piroplasmosis rests in protection against ticks, and, wherever the disease shows itself, destruction of ticks. In places free from ticks, and wherever ticks have been destroyed, it will be advisable to kill all animals infected. In trypanosomiasis, appliance of special chemical medicines offers the greatest chance of success. Moreover, endeavours should be made to destroy stinging flies, known as propagators, and infected animals should be killed.

Dr. THEILER (South Africa) submitted the following motions to the meeting at the close of the discussion on the subject, and they were carried unanimously:-

1. The Veterinary Congress at the Hague reaffirms the recommendations formulated at the Congress at Budapest, and impresses upon the Governments which have not yet organised a veterinary service the necessity for doing so with as little delay as possible.

2. It is necessary for the control of animal plagues in the colonies that all Governments concerned should materially encourage the study of such diseases. Since the biology of a disease must form the basis of all veterinary operations of an administrative character, it is desirable that wherever possible scientific veterinary investigators should be sent into territories where diseases which have not yet been investigated are prevalent, and since the work of these investigators will be of common interest both from the scientific point of view as well as from that of State veterinary medicine it should be communicated to all Governments concerned.

3. For the purpose of carrying out these proposals there should be

3. For the purpose of carrying out these proposals there should be established an International Bureau of Tropical Diseases of Animals, consisting of veterinary representatives from all the countries concerned, and the international bureau should publish a bulletia giving the results of all recent international publications dealing with tropical diseases of animals.

The Government Control of Sera and Bacterial Products and their Preparation by Government

was opposed by Professor E. LECLAINCHE (France), who defended the preparation of serums by individuals—that is to say, by the inventors themselves, those being the best people to improve them later. Other speakers were of opinion that preparation by the State would be desirable. The following resolution was unanimously adopted:

In default of direct preparation by the State of products of bacterial nature for the use of the veterinary profession, the preparation and the sale of these products should be placed under the control of the State.

Dr. E. F. BASHFORD dealt with

The Etiology and Pathogeny of Malignant Tumours.

He dealt with conclusions derived from the study of cancer which have been so lately published in THE LANCET that there is no need to repeat them, but he paid a full and grateful tribute to the assistance which cancer research had derived from veterinarians, amongst whom, he said, the name of Jensen will always be associated with the experimental study of cancer.

The Congress sat for six days, the closing address being given by His Excellency the Minister of Agriculture, Industry, and Commerce for Holland, who officially announced that the next International Veterinary Congress will be held in London in 1913.

BIRMINGHAM.

(FROM OUR OWN CORRESPONDENT.)

Annual Report of the Medical Officer of Health.

THE annual report of the medical officer of health is more than a mere collection of statistics; it is full of human interest and reveals considerable progress in the moral and physical well-being of the city. The general death-rate of 15.9 per 1000 was the lowest ever recorded, but this favourable statement is somewhat misleading, for the population of Birmingham has to an exceptional extent overflowed its boundaries, and the death-rate of what may be called greater Birmingham was 14 1. For some years there has been a very desirable movement outwards and the central parts of the city have been decreasing in population at a rapid rate. This is largely due to the improvement in means of transit and the pulling down of houses in order to build offices and works. Unfortunately the movement to the suburbs means the development of surrounding towns entirely due to the overflow of the Birmingham population. King's Norton and Yardley to the south have increased at the rate of 178 per cent. and 237 per cent. respectively, and districts on the north show a similar increase. From a purely health point of view it is unfortunate that the Birmingham population should have a multiplicity of authorities, and it is greatly to be hoped that some means may be taken to prevent overlapping. The birth-rate, 28.4, is almost the same as in the previous year (28.3), which was the lowest on record. The more highly infectious diseases were all, with the exception of whooping-cough, less prevalent than they have usually been during the preceding decade. The rate of infant mortality (144 per 1000) constitutes the lowest record, but one which is far from satisfactory. While the number of cases of typhoid fever was exceptionally low the disease was a state of the constitution of the of a severe type, 49 deaths having occurred among 193 cases. During the last quarter of the year there were 74 cases reported, and no less than 19 had a history of having consumed mussels shortly before the attack. There has been a marked decrease in the amount of typhoid fever during the last six years coincident with the conversion of the more objectionable of the pan closets, 8000 of which still remain. The 198 certified midwives reported having attended 9244 births, equal to 47 cases per midwife. A point of some importance is that the fees have within the past year or two increased by about 2s. 6d. per case, but in order to obtain an income of 30s, per week a midwife would have to attend over 200 patients per year. This indicates the unattractiveness of this calling as a sole means of support. To carry out her duties properly a midwife cannot attend more than 200 labours in a year. On this basis 50 midwives could carry on the work of the 198 now practising. It is expected, therefore, that within a few years there will be a considerable diminution in the number of women practising. Much time has been devoted to measures tending to check the prevalence of tuberculosis. A commencement has been made in an endeavour to eradicate tuberculosis from a number of herds of cows supplying milk, so as to provide a supply of tubercle-free milk for hospitals and other institutions, and ultimately to anyone who is willing to pay a reasonable price for it. The municipal sanatorium on the Cotswolds is now proving a great boon to the consumptive workers.

Soarlet Fever.

Scarlet fever continues to increase in the city, there having been no fewer than 92 fresh cases the week before last, as compared with 82 during the previous week. The number of patients in the fever hospital is 483. The case mortality is not high, for there were only three deaths last week, for which period the general death-rate was $14\cdot 2$ and the zymotic death-rate $2\cdot 5$.

The University.

The matriculation examination, which is held twice annually—viz., in July and September—has just been completed for this year, and the total number of candidates again shows a very satisfactory increase. In 1907 the total was 433, last year it rose to 491, and this year to 568. Although many other examinations are accepted as qualifying for entrance to the University and the Birmingham matriculation is similarly accepted by other universities, yet the numbers indicate that the entry for the coming academic year should easily maintain the healthy rate of growth characteristic of the last few sessions.

Post-Graduate Demonstrations.

A course of post-graduate demonstrations will be given by members of the staffs of the General and Queen's Hospitals during October, November, and December.

Sept. 28th.

LIVERPOOL.

The Annual Report of the Medical Officer of Health: The Diminution of Tuberoulosis.

THE section of Dr. E. W. Hope's annual report dealing with the incidence of tuberculosis in the city is both interesting and instructive. From the report of a special commission of inquiry made 60 years ago it appears that at that time 100,000 of the inhabitants were living in houses so aggregated and so constructed as to be unfit for human habitation, and that 40,000 were living in cellars. Light and ventilation were sadly deficient, the houses and courts were dark and filthy, and the cellars and lodging-houses were greatly overcrowded and without supervision. The condition of the schools was wretched in the extreme, dark, confined, and dirty; they were used as a dwelling, a dormitory, and a school-room, whilst the atmosphere was most offensive. There was an absence of water-supply, drainage, and scavenging. Since this gloomy picture was painted huge sums of money have been spent in Liverpool in demolishing insanitary property and replacing it by wholesome dwellings, and in other sanitary improvements, with the result that during the last 43 years alone the mortality from all forms of tuberculosis has fallen to one-half. The mortality from phthisis and diseases of the lungs in the demolished areas was then notorious, but now, in the corporation dwellings mostly inhabited by the same families, and notwithstanding their history, the mortality from the same disease was during 1907-08 actually 1.35 per 1000 lower than that of the city taken as a whole, and very considerably below that of the districts in which the dwellings are situated. From this Dr. Hope draws the conclusion, and many will agree with him, that the most effective way to spend public money in order to cope with disease is to abolish the slums, to purchase the sites, and to erect sanitary dwellings thereon.

The University of Liverpool: The Openiny of the Faculty of Medicine for the Session 1909-10.

The inaugural address will be delivered in the Arts Theatre of the University on Tuesday, Oct. 5th, at 4 P.M., by Mr. Charles A. Ballance, M.V.O. The members of the faculty and other graduates are requested to wear academic dress. The lecturer will be entertained in the evening to dinner by the members of the faculty at the University Club.

The New Governor of Queensland and the Liverpool School of Tropical Medicine.

At the Liverpool Club, on Sept. 27th, Sir Alfred Jones, K.C.M.G., president of the Liverpool Chamber of Commerce, and chairman of the Liverpool School of Tropical Medicine, entertained at luncheon Sir William MacGregor, who sails on Oct. 15th to take up his new duties as Governor of Queensland. Amongst those present were Professor Ronald Ross, C.B., Major R. Bird, I.M.S. (professor of surgery at Calcutta University), Dr. A. Kinghorn, and Dr. Anton Breinl. Sir William MacGregor, in reply to the toast of his health, said that he had known the Liverpool School of Tropical Medicine from its inception. He had spent 31 years in the service of the country in the tropics, and he thought that few people had had a better opportunity than he had of seeing how much an institution of this kind was wanted in the world. Few men

could better appreciate the amount of good it had been able to do. He had had the opportunity on Sept. 25th and that day of renewing his studies at the school, and what he had been able to learn had been of considerable use to him and would be of great value to others. It was a great school, not on account of its size, but because it was the nucleus which was going to scatter broadcast tropical schools all over the Empire. The beginning of the Liverpool School of Tropical Medicine they owed from a scientific point of view to Major Ross, but to Sir Alfred Jones they were almost equally indebted. He looked upon the school as being the pioneer of all other schools of this kind that were to follow.

The Health of Liverprol.

The gradual diminution of the death-rate of the city is very gratifying. Last week the rate of mortality was as low as 15.8 per 1000 of the population. Dr. Hope ascribed the diminished death-rate to two causes. He said it was partly due to the weather and partly to progress. In this connexion the word "progress" means a great deal to Liverpool. It represents a large amount of money expended in improving sanitation, in an elaborate cleansing system, in an abundant water-supply, and in the comprehensive scheme of demolishing slum properties, replacing them with wholesome artisan dwellings, to which I have just alluded above.

WALES.
(From our own Correspondent.)

Cardiff Medical School.

ALTHOUGH it has been possible for some time past for a medical student to pass the early years required by the medical curriculum in attendance at University College, the fullest use has not been made of the clinical material available in the hospitals of the town. The proposed enlargement of the infirmary by the addition of an extra wing for in-patients and the recent addition of an out-patient department will increase enormously the existing facilities for clinical instruction. In this connexion it is satisfactory to find that of the additional grant of £15,000 which has been made by the Treasury to the University £1500 have been allocated to the medical school.

Asylum Accommodation in Glamorgan.

When it is remembered that the increase in the population of the administrative county of Glamorgan is approximately 6000 annually it is not surprising to find that there is some difficulty in keeping pace with the increase in the number of when the Commissioners in Lunacy visited the Bridgend Asylum last year they reported that although the day space in the institution was sufficient for 1548 patients and the night space for 1693, there were in the asylum 1727 patients, the excess being entirely on the male side. The removal of all the Cardiff patients to the new asylum of the Cardiff corporation has thus had little apparent effect in lessening the overcrowding at the county institution, and the few patients who are still there from Swansea and Merthyr cannot appreciably increase the difficulties of the visiting committee. The councils of these two boroughs are steadily progressing towards an agreement to provide an institution for the joint use of patients from the respective towns, and alternative sites have been selected for the necessary buildings.

Infantile Mortality in Glamorgan.

The rate of infantile mortality in Glamorgan in 1907 was 136 per 1000 births, and it is to be regretted that it is not possible to report the same favourable record for 1908, when the rate was 152 per 1000 births. In Margam, where there is a population of some 12,000 persons, the appalling rate of 279 per 1000 was recorded, and in Aberdare the rate was 212 per 1000. In his recently issued annual report the medical officer of health for the county (Dr. William Williams) points out that although this mortality is generally acknowledged to be preventable, yet it is dependent to a great extent upon climatic and meteorological conditions. The work of reducing the mortality he considers should not be left entirely to sanitary and education authorities, but parents should be made to realise their responsibilities, while social, philanthropic, and religious institutions should take a part in

carrying out remedial measures. Much more might be done by sanitary authorities in providing for the more thorough scavenging of organic refuse from the vicinity of dwelling houses. The existence of huge accumulations of household refuse in many parts of the colliery districts must be considered as a fruitful cause of the high infantile mortality, and it is not a little astonishing that so few districts in Glamorgan are provided with the means of destroying refuse by burning. In Barry a destructor has been in use for some years, and in the Rhondda valleys a small one was installed some nine years ago, but elsewhere none have been provided, although at Pontypridd one is in course of erection, and at Aberdare sanction to the necessary loan is being awaited, and when it is received the works will be proceeded with. In the latter town it is proposed, if possible, to utilise the destructor for providing steam power to an electric lighting plant.

Sept. 28th.

SCOTLAND.

(FROM OUR OWN CORRESPONDENTS.)

Outbreak of Enterio Fever in Glasgow.

An outbreak of enteric fever has taken place on the south side of Glasgow in a distinctly limited area of the city which lies near the river. During the week ending Sept. 11th seven cases were reported to the medical authorities. Thereafter the number of cases steadily rose until 48 patients were under treatment. For more than a week no new cases have occurred, and it is hoped that the outbreak, which was peculiar in its self-limitation, is at an end. It is a little difficult to say what the source of the trouble was. has been shown by the medical officer of health for the city that the families affected had been supplied with milk from different shops, but all or most of the supply was sent from the same wholesale dairy. The difficulty of tracing was increased by the fact that this dairy received milk from about a score of farms situated in the western and south-western counties. So far no recent case of the disease has been discovered at these farms, but the authorities are still investigating the possibility of a "carrier" being responsible for the mischief.

The Colliery Surgeon: a Test Action.

An action of much interest throughout the mining communities of Scotland has just been decided in Dunfermline small debt court by Sheriff Shennan. The action was of the nature of a test action, and the sum sued for was 1s. 6d. Previous to the raising of the action a correspondence passed between a representative of a number of miners in Kelty and the Fife Coal Company in regard to the appointment of a colliery surgeon, but the parties having failed to come to an understanding the present action is the result. The pursuer, who is president of the Fife and Kinross Miners' Association, stated that he had been several years in the employment of the defenders—the Fife Coal Company. Under the contract of service between the pursuer and the defenders, the former authorised the defenders to deduct from his wages for the colliery surgeon, Dr. A. G. Carment, the sum of 6d. per fortnight for medicine and medical These arrangements continued in force until attendance. Dr. Carment left the district on July 1st of the present year. On the 9th of the same month the pursuer notified the defenders that he objected to any further deduction for medicine or medical attendance, and since that date he had employed and paid another medical man selected by himself. Notwithstanding that, the defenders had fortnightly deducted 6d. from the pursuer's wages for medicine and medical attendance. Pursuer further averred that the deduction was illegal at common law and contrary to the Truck Act of 1831. He claimed that the very utmost the employer could have said was that unless he was going to put himself under the surgeon nominated he must leave the colliery, and the employer did not take this course. For the defenders it was maintained that by the conditions of employment under which the pursuer was engaged each workman undertakes to pay the usual charges customary at the works, including house rent, fire coal, and medical attendance. The sheriff in his judgment said there was no doubt that under Section 23 of the Truck

provided that the agreement for such deduction was in writing and signed by the workman. It was admitted that several pay lines signed by the pursuer as receipts embodied an authorisation to the defenders to deduct "from my wages in future so long as I am in your employment the amount of my house rent, also the sum paid by you for medicine and medical attendance, &c." On July 13th and 27th and August 10th pursuer signed pay lines containing the authorization and according to risation and accepted the balance of wages. Prima facie the pursuer was barred by the terms of his own receipts. If pursuer objected to the deduction of 6d. he was bound, in order to keep the matter open, to state his objection to the statement of wages within two working days after pay. Not having done so, he was tied down to the statement in the pay ticket as conclusive, and could not possibly recover any of the sums for which he sued. Defenders were therefore granted absolvitor, with 10s. expenses.

Sept. 28th.

IRELAND.

(FROM OUR OWN CORRESPONDENTS.)

The Erection of Labourers' Cottages.

An inquiry was opened last week into an application made by the Rathdown No. 1 rural district council for a loan of £28,200 to be applied in the erection of 119 cottages under the Labourers Act. The inspector of the Local Government Board opened the proceedings, and the solicitor for the council read extracts from the report of the Board's inspector which was furnished in 1902, in which the latter stated that the houses for the labourers in a portion of the district were a menace to the lives of the inhabitants. The council sought to erect only those cottages which were actually wanted by bona-fide labourers, and, speaking from personal experience (he added), that could not always be alleged regarding such applications throughout the country. The council had worked the previous schemes in such an efficient manner that the rate in aid of the expenditure did not exceed 1s. 4d. in the £. Expert evidence was then given regarding the outlay. The cost of evidence was then given regarding the outlay. each cottage of the 119 proposed was estimated at £234 6s. 8d. The inspector said that while he was prepared to expect that the expense would be considerable in such a district as Rathdown, he did not see why it should be greater than that incurred in the erection of such cottages by the North and South Dublin councils, and added that without reduction of the estimated expenditure he was afraid that the loan would be refused, as the sum of £4,500,000 voted by the Government was getting used up, and the Local Government Board desired to stretch the remainder so as to procure the erection of the greatest possible number of cottages. The fact that the question is, as shown in the evidence, already one of more than seven years' standing, is surely strong evidence of the necessity for an early solution. The dreadful state of the hovels in which the poor Irish labourers have for many generations been doomed to drag out the indoor portion of existence is a distressing fact which fixes the attention of every observant visitor to this country.

The Beifast Natural History and Philosophical Society.

At a special meeting of this society held in the Belfast Museum on Sept. 24th a resolution was passed authorising the council to make application to the Commissioners of Charitable Donations and Bequests for Ireland to allow them to transfer upon loan to the corporation of the city of Belfast, upon such terms as may be arranged, the various collections in the old Belfast Museum. The corporation has arranged to take them over and has struck a rate of $\frac{1}{2}d$. in the £, which would yield £2900 on the present valuation, with the view of amalgamating the society's collection with their municipal collection, and steps are being taken to arrange for the provision of museum buildings worthy of the city in which the joint collections will find a home. John Byers has been elected President for another year.

The Nuisance on the Foreshore of Belfast Lough.

The executive committee of the Belfast foreshore committee has issued a report in reference to the work undertaken by it since its appointment on Oct. 20th, 1908. At the outset the main reasons leading up to the appointment of the committee are given, and mention is made of the various

schemes put forward by the city corporation in 1902, 1906, and 1907 for the purification of the city sewage. The Local Government Board having informed the Belfast corporation that it would not give its certificate under the Act of 1899 for any system of purification until the Board should have experience of its working for a lengthened period, and that it must have ample opportunity of judging of its efficiency by the effect it would have on the growth of the weed (ulva latissima) in the Lough before it could give its approval, a joint meeting of the improvement and public health committee requested the Royal Commission on Sewage Purification, on May 25th, 1909, to submit the names of six persons competent to determine what further purification, if any, of the sewage discharged at the main outfall works is necessary in order to comply with the requirements of the Act of 1899. Experts appointed by the Royal Commission are now at work with the object of recommending some scheme of purification. Meanwhile, the corporation intends to promote a Bill in Parliament during next session, and the executive committee of the Belfast foreshore committee intends to watch carefully the interests of the property owners and ratepayers so as to ensure a proper scheme being undertaken, and one which will put an end to the existence of the "foreshore nuisance."

The Salaries of Dispensary Medical Officers.

The Local Government Board has written to the Limavady guardians to the effect that it cannot approve the scale of graded salaries adopted by the guardians in December, 1904, which the Board was unable then to sanction, and asking them to reconsider the entire question and to try to arrive at an amicable settlement with the medical officers on the subject. The Board urged that in any proposal that might be submitted provision should be made for granting to the existing medical officers such immediate increases to their salaries in recognition of their past services as would enable them to share to an appreciable extent in the benefits of the improved scale during the remainder of their careers in the service of the union. Dr. B. MacCarthy, medical inspector to the Local Government Board, advised the guardians at their meeting on Sept. 27th to do what the Local Government Board advised, and also to grant the two retired medical officers allowance under the civil service scale, but the guardians decided to adhere to the scale of salaries formerly adopted by them.

Women's National Health Association: an Interesting Meeting in the West.

A large and representative meeting was held at Clifden on Sept. 21st for the purpose of conveying an expression of the sincere sympathy of the people of the district to the Countess of Aberdeen in the bereavement caused by the death of her brother, Lord Tweedmouth, "who, like Her Excellency, was always a true and constant friend of Ireland." The meeting was presided over by His Grace the Most Rev. Dr. Healy, Catholic Archbishop of Tuam; and among the other prominent personages present was the Protestant Bishop of Tuam, Dr. O'Sullivan. After the unanimous adoption of the resolution of sincere sympathy, which was the primary object of the meeting, the following propositions were also carried with acclamation:-

with acciamation:—

1. That we, the people of Clifden, in public meeting assembled, hereby place on record our high appreciation of the noble efforts of Her Excellency Iady Aberdeen to stamp out from amongst our people the dreadful soourge known as the "White Plague," and we heartly thank Her Excellency for sending to this district the "Phenix," accompanied by her lecturers, whom we cordially welcome to our town.

2. That we hereby establish a branch of the Women's National Health Association for the Clifden and surrounding districts for the purpose of cooperating with Her Excellency in the good work of combating the ravages which are being wrought in our country by the terrible scourge of consumption, and to secure for this district the advantages which followed the establishment of such branches else-

advantages which followed the establishment of such branches else-

where

To those who know the temper of the "wild West" this meeting will seem to mark an epoch in the history of a distracted country. It is an incontrovertible indication of the methods by which the best feelings of an emotional people can be focussed in the right direction. The "crusade" organised by Lady Aberdeen was bound to elicit a good deal of unfavourable comment, as every crusade does, and was also bound to carry with it the factors of inconvenience to many individuals and serious grievance to some others, as every crusade has also done, but it has now arrived at a stage at which its educational value cannot be disputed. This must be admitted even by those who have been most intensely opposed to compulsory notification.

Sept. 28th.

PARIS.

(FROM OUR OWN CORRESPONDENT.)

The International Association of Padiatrics.

THE International Association of Pædiatrics has recently been founded for the purpose of creating a bond of union between the surgeons who in various countries devote themselves to this specialty. From the nature of its composition the association is naturally divided into several sections corresponding to the nationalities represented, and its affairs are managed by a committee consisting of delegates appointed by each nation. The first congress of the association will be held in Paris in 1910, on the Thursday, Friday, and Saturday before Easter. No communications will be brought before this meeting, except such as relate to the questions selected by the international committee and placed on the official programme. Each of these questions will be dealt with in discourses (rapports) entrusted to two or more medical men belonging to different nations.

Noximis Inscots in Madagascar.

The biting and stinging insects (insectes piqueurs) of Africa have been made the subject of careful study by M. Surcout, and at a recent meeting of the Society of Tropical Medioine and Hygiene, he presented a very detailed memoir on the tabanidæ of Madagascar. Certain differences which exist between these insects and the tabanidæ of Africa seem to support the view that the fauna of Madagascar are partly of Indo-Malayan origin. M. Surcouf described the new genus Bouvierella and numerous new species, thereby enhancing the importance of his memoir on biting, stinging, and blood-sucking insects, a knowledge of which is rapidly becoming more and more necessary for medical men practising in the colonies.

Inorease in Medical Fecs.

A commission, composed of delegates from the general council of the district medical societies (sociétés médicales d'arrondissement), from the Syndicate of Medical Men of the Seine, from the Paris Medical Syndicate, and from the Medical Society of the Fourth Arrondissement, has recently, after a long discussion, unanimously adopted the following

after a long discussion, unanimously adopted the following resolution:—

The general council of the district medical societies, the Syndicate of Medical Men of the Seine, and the Paris Medical Syndicate, representing all the medical men practising in Paris and the suburbs, have agreed to consider the question of raising medical fees. They have acknowledged and decided that it is necessary to increase the scale of medical fees by at least one-third more than the current rates for ordinary visits and consultations as charged at the present time. Each district shall decide what is the lowest fee to be charged in that district. For visits either in urgent cases or in the evening, or on Sunday, higher fees will be charged than for ordinary visits. A scale of minimum charges for special work in ordinary practice shall be drawn up.

Re-education in Psychotherapy.

At the annual meeting of the Society of Hypnology and Psychology, which was held in Paris under the presidency of Dr. Jules Voisin, the methods of re-education in psychotherapy formed the subject selected for discussion. It was stated that the statistics of the reformatory school of the Salpêtrière Hospital showed that the principal causes of juvenile crime were (1) bad example and the want of education; and (2) intellectual defects of hereditary origin (mental debility and perversion). Measures directed against alcoholism, syphilis, and tuberculosis were the first requisite for improving the present state of things, and moral education must also be considered. In discussing the use of hypnotism in the re-education of the will power, M. Berillon said that in his opinion the use of hypnotism was at once legitimate and distinctly indicated in the treatment of such patients. Moreover, in a great number of occupa-tions in which manual dexterity and constant training played an important part any bodily injury had a most unfavourable influence. It very often happened that the interruption of habitual activity and the restraint of motion inevitable in the treatment of a bodily injury brought about a kind of "mental ankylosis" which formed an obstacle to the recovery of aptitude for the patient's occupation. If it was desirable to urge these individuals not to neglect any opportunity of keeping themselves proficient in their several avocations, it was just as necessary to provide for their reeducation when they felt a sensation of inability to resume work. These new applications of psychotherapy were of importance especially to musicians and art-workers, who were

predisposed to hypnotic suggestion. They also formed the most rapid and efficacious means of treating certain forms of loss of muscular power in which the patients if left to themselves would seldom make any progress towards recovery.

Treatment of Nooturnal Incontinence of Urine.

M. Chavigny has recently shown a man whom he had quite successfully treated for nocturnal incontinence of urine by means of Genouville's "re-educating" apparatus. This consisted of two metallic plates, having between them a thin layer of absorbent wadding and connected to a galvanic battery. The plates thus arranged were placed under the person's pelvis, and as soon as the wadding became wetted with urine the circuit was completed and a bell rang. For the bell M. Chavigny has substituted two conductors in contact with the pubic region, and as soon as any urine was passed the person received an electric shock which woke

Hospitals in Camps of Instruction.

As a result of visits which he has lately made to certain camps of instruction, the Under Secretary of State for War has resolved to establish hospitals (infirmeries-hôpitaux) in all camps where they do not as yet exist. These hospitals will enable sick and wounded men to be treated on the spot, thereby sparing them the fatigue and possibly injurious effects of the journeys which would otherwise be necessary. Sept. 28th.

BERLIN.

(FROM OUR OWN CORRESPONDENT.)

Education and the Health of German Military Recrusts.

An interesting report on the bodily condition of the young men qualified to serve in the German army as so-called "volunteers" has been compiled for the Army Medical Department by two military medical officers, Dr. Nicolai and Dr. Schwienig. It may be stated by way of explanation that in the German army the word "volunteer" does not convey the same meaning as it formerly for many years had in connexion with the British forces. Conscription having been in force in Germany for nearly a century there is no opportunity for volunteer service in the strict sense of the term. A German volunteer is a man who has received his school education at a gymnasium, a real-gymnasium, a realschule, or other higher school, where he must have successfully passed in at least the third class—in a word, he is a man of better education than the average conscript. He enjoys the privilege of having to serve only one year instead of the two or three years of the ordinary conscript, and is eligible to become an officer of the reserve. He may also for the purpose of his service select both the regiment and the period of service which he prefers until he reaches his twenty-fifth year, whereas the average man must begin to serve in his twentieth year and must join any regiment to which the military authorities choose to send him. The above-mentioned report, quoted in the Berliner Klinische Wochenschrift, compares the bodily condition of the pupils of the various grades of schools with each other and partly with the average conscript. It gives the results of observations made on 52,650 young men who presented themselves for service as volunteers during the years 1904 and 1906. The report states that the percentage of men fit for military duty was greater among the volunteers than among the conscripts. Among the volunteers the greatest number of men unfit for service occurred in the pupils of the classical gymnasia; next in order came the pupils of the real-gymnasia (schools in which less classics but more modern languages and mathematics are taught); and after them came the pupils of the realschulen (schools in which there is no classical teaching, the principal subjects being mathematics and physics). Men with a comparatively short school attendance were on an average more fit than those whose school attendance was longer. Of the causes of unfitness the principal proved to be general debility, then came diseases of the heart and of the great vessels, anomalies of refraction, anomalies of the joints and extremities, and diseases of the lungs. The most marked forms of disease of the lungs leading to permanent unfitness for military service were observed in the pupils of the gymnasia. General debility was the most frequent cause of unfitness in Berlin, in Posen, in Silesia, and in the

Hanseatic cities, but it was less frequent in Alsace-Lorraine, Franconia, Pomerania, East Prussia, and Thuringia, whilst diseases of the heart were preponderant in Bavaria, Würtemberg, and Silesia. Of the former pupils of the gymnasium 47 per cent. had anomalies of refraction, especially myopia. The kingdom of Bavaria had the greatest number of men with anomalies of refraction. Dr. Nicolai and Dr. Schwienig state that the statistical tables show such an unsatisfactory condition of the eyes among the pupils of the higher schools that measures must be taken to counteract this failing.

Gonorrhæa in Female Children.

Dr. Bendig of Stuttgart, writing to the Münchener Medicinisohe Woohenschrift, gave an account of epidemics of gonorrhea among children in two institutions, one of which was a sanatorium for girls of the poorer classes. Of 40 girls who were between seven and ten years of age 15 contracted the disease, which was in the first instance introduced by a girl aged eight years. The infection was spread by means of the arrangements made for bathing, as it was the practice for two children to bathe together in the same water and they sometimes used the same towel indiscriminately. When the disease was discovered the children were conveyed to the Stuttgart Hospital. The external genitalia proved on examination to be in a swollen state, the vulva was occluded by the swollen labia, and a stream of pus appeared when the latter were separated. The children were feverish and complained of prickly sensations, of strangury, and sometimes of abdominal pain. The treatment consisted in the administration of santal oil and in covering the vagina with a layer of cotton-wool in order to keep the children from touching the parts and thereby incurring the risk of producing gonorrheal ophthalmia. Irrigation of the vagina by solutions of permanganate of potash and of protargol was also employed and the urethra was brushed with ichthyol. In some children although the agenta symptoms disappeared tolerably soon although the acute symptoms disappeared tolerably soon, the disease became chronic and was accompanied by a mucous discharge which contained gonococci. cases the treatment was interrupted for about a fortnight, the result being that the acute symptoms reappeared. Irrigations with protargol were accordingly recommenced, and plugs of wool moistened with protargol and glycerine were put into the urethra, where they were left until the next micturition. The treatment was successful, but in several cases relapses occurred, sometimes even ten weeks after the patients had been discharged from the hospital. In the result all the children recovered completely, although one of the girls required continuous treatment for 279 days. No complications occurred—neither endocarditis, ophthalmia, nor perimetritis. For the prevention of such disasters it was recommended that children previously to being sent to sanatoriums should be examined for the presence of gonorrhoea. They should also bring with them their own towels and no bath should be used for more than one child at a time.

An Epidemic of Milk-borne Enterio Fever.

An epidemic of enteric fever lately broke out at Cassel, in the province of Hesse, and within ten days not less than 170 cases occurred, of which only two have as yet proved fatal. The epidemic was spread over the whole town, as if by an explosion. On careful examination the point of origin was discovered in the municipal dairy, where the presence of enteric fever bacilli was recognised in a large tank containing 7000 litres of milk. It was then ascertained that two of the people employed in the dairy were the first to become ill, but it was not certain whether they had been the means of contaminating the milk or whether they were the first victims, the milk having been previously infected from other sources. The municipal authorities were naturally alarmed by the sudden spread of the disease; they have arranged for the reception of a considerable number of enteric fever patients by provisionally establishing some Döcker barracks. The water from the river Fulda and from the waterworks proved to be free from enteric fever bacilli, but the public bathing-places have nevertheless been closed.

Infantile Paralysis.

A form of infantile paralysis has become prevalent in several towns in the Rhenish province. From Gladbach ten cases were reported showing partly monoplegia, partly hemiplegia, partly paraplegia. All the cases happened within the same district of the town, but there has not been any

instance of two cases occurring in the same house, although it has twice happened that brothers and sisters showed premonitory symptoms, such as pyrexia, vomiting, and drowsiness. The children were all from one to two years of age. Also in Mülheim on the Rhine, in Styrum, Alstaden, and Oberhausen a total of 45 cases occurred, and the disease is on the increase in Hamburg. Bacteriological examination proved negative.

Sept. 27th.

ITALY.

(FROM OUR OWN CORRESPONDENT.)

The Italian Association for the Promotion of Science.

THE week now closing has witnessed the inauguration and subsequent sittings of this the third meeting of Italy's counterpart to the British Association. Its seat is Padua and its presiding spokesman, the professor of constitutional law in the University of Rome, Signor Luigi Luzzatti, member of the Chamber of Deputies, where on all questions of education and finance he maintains the best traditions of his predecessors of the Right, Quintino Sella and Marco Minghetti. Reference to the discussion in the various sections-those of biology in particular—may stand over for the present; but Signor Luzzatti's address, covering as it does the whole field of "science, philosophy, and the school," deserves more than a passing notice. It was indeed a brilliant performance, singularly opportune in Italy, whose urgent duty it is to combine and mobilise her forces, educational and financial, if she is to regain the post she once held in inductive research and academic exposition. magnitude of the task confronting her may be estimated from the leeway she has to make up, beginning at the very outset of scholastic training. On this Signor Luzzatti gave some details reflecting severely on the perfunctoriness with which the schools, primary and secondary, prepare for intelligent citizenship and a fortiori for professional life. "La scuola Italiana deve essere rifatta" (the school in Italy has to be remodelled and remade), as he amply showed, and then, having postulated such a consummation, he drew in bold, comprehensive outlines a plan of cam-paign by which the national genius might develop in the interests of science and of progress, intellectual and moral. One danger to be guarded against, particularly in a renascent state like that of Italy, was, he pointed out, a "premature specialism," issuing in a truncated or lop-sided mental growth and attitude, disastrous to the attainment of what a great English physician happily termed "the complete professional mind." The danger, indeed, is not one which menaces Italy only. Other nationalities, far ahead of her in education and expert development, are already becoming cognisant of it, and their misgivings could not find more eloquent or convincing expression than that given to it by Signor Luzzatti, whose address, if only for this consideration, merits attention far beyond the audience first privileged to hear it.

The New Pharmacopæia.

The Ministry of the Interior, by decree dated Sept. 15th, has approved the revised text of the official Pharmacopæia for national use in substitution of that approved by the same Ministry on March 1st, 1902. The new issue sets forth in tabular form: 1. The medicaments with which every pharmacist must, de riqueur, be provided. 2. The apparatus and utensils indispensable in each pharmacy. 3. The substances which must be kept under special designation in cabinets under lock and key. 4. The medicinal substances entered in the Pharmacopæia which ought to be kept by the pharmacist excluded from the light. 5. The substances entered in the Pharmacopæia, which may be sold by anyone (except, of course, poisonous substances), but never in quantity below the measure established for each. 6. Alimentary substances and those in domestic use entered in the Pharmacopæia, of which the sale is free (poisonous substances as before excepted). 7. The maximum doses for the adult, beyond which the pharmacist is forbidden to dispense, except in special cases under express sanction of the practitioner. To the above "tables" is added a list of the "specialità medicinalis" entered in the Pharmacopæia itself. The above regulations may seem to the outer world rather meticulous, but no one

familiar with the law press of Italy and the frequent (sometimes fatal) "sbagli" or mistakes it records can be other than thankful that the Home Office has been thus minute and precise in its surveillance of the pharmacist's métier.

Arrest of a Pseudo-Practitioner.

The police have laid hands on one Giovanni Pedrelli, hailing from Sasso, a township on the Milan-Bologna-Florence line, charged with "truffa, falsita, ed esercizio arbitrario della professione medica" (fraud, quackery, and unqualified practice of the profession). He had aroused suspicion, inter alia, by the eccentric prescriptions he put his name to, by his careful avoidance of anything like discussion with pharmacists or brother practitioners, and by his outrageous misuse of medical terminology in diagnosis. Asked by the prosyndic to produce his credentials he handed him a "certificate" of the University of Modena, adding that he had lost the original diploma on one of his many absences abroad, some of them in the capacity of surgeon on board an Italo-American liner. Shortly thereafter there came from Modena, as well as from the other qualifying schools throughout the kingdom, affirmations from the registrars that for 40 years no graduate or licentiate had issued from their halls under the name of Giovanni Pedrelli. Then followed the interrogation after his arrest, in the course of which he equivocated, and finally confessed that he was neither graduate nor licentiate, but had passed one session as a first year's student at Bologna. He is now awaiting sentence, and meanwhile the population of the district in which he "practised" is loud in its censure of the official supineness which placed them at the mercy of an adventurer whose rôle, however appropriate in the pages of "Gil Blas," is a scarcely creditable anachronism in the Italy of to-day. Sept. 25th.

CHINA.

(FROM OUR OWN CORRESPONDENT.)

Anthrax in China.

THE subject of anthrax and its prevention, as far as the export of infective hides from China is concerned, seems almost a hopeless one with regard to any practical amelioration. There seems little doubt that human anthrax is more prevalent in England than it is here. For the past halfdozen years, since my attention was first drawn to the absence of anthrax among Chinese, I have been on the lookout for cases and have never yet personally seen a case. I have only been able to find a sum total of three cases coming under foreign treatment, two of these being Europeans. One was a French veterinary surgeon who, on making a necropsy on a mule, scratched his finger, which, though treated by sublimate dressing at the time, caused his death in four days; another was a supervisor in a hide and bristle factory; and the third, a Chinese pedlar on a visit to Peking, had no history of contact with hides or wool, but came to the Peking Hospital with the malignant pustule, from which he died. In all three cases the bacillus anthracis was found. Some time ago a series of inquiries were made by the native staff of the British Charitable Hospital, Peking, among workers in the trade here; they described the disease and asked for instances of its occurrence, but their failure to get information in any way pointing to it leads one to infer that anthrax in China is by no means the danger it is among workers in England. This is all the more remarkable, as China heads the list of countries-of-origin of infective hides; in fact, her exports are regarded in the trade as particularly dangerous. The Home Office medical authorities have taken as active steps as possible by means of stringent factory legislation to deal with the question, but the incidence of anthrax does not seem, as far as one can gather from the returns, to diminish. It therefore appears that the only effective method would be to deal with the source and origin of infection. In China at present this is not possible, and so far as one can see there is little hope of its ever being different. The conditions here under which the animals live (the conditions of soil, temperature, decomposing vegetable matter, moisture) are all favourable to the bacillus and to outbreaks of cattle anthrax. An instance of this is now being furnished at Hsuchoufu- a district lying between Peking and Shanghai. I have received a letter from a medical friend there,

who reports as follows: "The disease, which has been destroying cattle throughout this Fu, continues its ravages, though with diminished virulence, probably because there is now a scarcity of susceptible cattle. The mortality is now a scarcity of susceptible cattle. The mortality has varied from 50 to 75 per cent. of the infected animals. To determine the extent of the disease I made inquiry as to the number of hides exported during the first three months of this year. They say that more than 260,000 left this city, and for the whole Fu half a million would not be too high an estimate. As no cattle are being slaughtered this represents, approximately, the loss of cattle from the plague. The particular form that the disease assumes in this locality tallies exactly with the description of the pneumonic form of anthrax. All recognise it as highly contagious and drovers avoid taking their cattle through infected villages. It is asserted that several deaths among men followed the eating of flesh killed by this disease. I am not able to vouch for the truth of this report but it does not sound unreasonable. In the mission hospital, however, there has been no case of The foreign firms that export hides, wool, local anthrax." bristles, and hair are in the hands of Chinese middlemen who roam about the interior buying here and there from the agricultural classes. I have been over some of the factories in Tientsin (the centre of a large trade in this material) and have observed the steps they take to clean the stuff before its export. Bristles and hair are thoroughly well boiled in soda solution, wool is rough carded and shaken as free of as much dust as possible by machinery, and hides are sorted out and packed with naphthaline. Chinese workers in these factories seem to escape the disease, though they freely handle the skins. The exporters maintain that any further disinfection than is now given would spoil their goods and increase their expenses to such an extent as to make them seek the markets of other countries. A member of one of the biggest firms in North China wrote me some time ago: "I find that from the years 1902-1906 our own particular business is as 5 (U.S.A.) to 1 (London) and has been going downhill as follows: London, 1902-3, took 43 per cent.; 1903-4, 30 per cent.; 1904-5, 24 per cent.; 1905-6, 15 per cent.; and this despite the fact that we have our London office and can out things down as fine as any one." Thus it would appear that our Home Office authorities must feel their limitations in demanding any efficient sterilisation at the port of export. The real difficulty does not lie with the bacillus anthracis but with its spores, whose natural resistance is increased by their being embedded in the grease and dirt of the material while it is being dealt with in wholesale bulk in China. can be little doubt that the passage home through the Indian Ocean and the Red Sea in the warm hold of a ship is all-conducive to their propagation and preservation, so that when the time comes for bristles and hair being carded and separated out by workers at home these spores are liberated in an active condition ready for human infection to a much greater extent than is the case in China. Such preventive remedies as inoculation of cattle with attenuated vaccines are obviously impossible in such a huge continent as this, with the beasts so widely scattered in the far-off interior, and if it has been found impossible to sterilise horsehair in bulk at 253° F. for 45 minutes or to effectually kill the spores by any known disinfectant in such quantity as to allow of its use commercially, and of such power as not to destroy the material, it simply means we have reached a point where we know that we must put up with the import. of actively infective bales and thus rely on the precautions that can be legally enforced in England. It has been suggested by Dr. T. M. Legge, H.M. Medical Inspector of Factories, that a central disinfecting station might be erected at the Port of London near the two warehouses where practically all the horsehair and bristles that come into the United Kingdom are delivered. This would require to be on a very large scale if all the material in bulk were to be so thoroughly separated out, cleaned, and disinfected that the virulent and numerous spores could be effectually sterilised. Exporters in China have told me they are fully alive to the dangers of the trade and are willing to meet in every reasonable way any suggestions they may receive which would enable their infective material to be disinfected locally and packed in a way less dangerous to home workers.

Famine and Flood.

In the absence of a census or any official returns one cannot tell the actual numbers of Chinese who meet their

deaths by such fortuitous circumstances as famine, flood, and epidemics which all recur annually throughout the empire. "Many thousands" have died from famine in the province of Kansu, where there has been no good rainfall for seven years, culminating in a prolonged drought this summer. streets of Peking are placarded with pictorial appeals to the charitable showing the emaciated farmers and their families eating weeds in the fields. One wood-cut depicts the old mother of the household being cut up for food, bits of her limbs being placed on a platter by the fireside ready for cooking—to such straits are the people said to be driven. Kansu is in the extreme north west of the empire. In Mid-China a loss of life estimated at "several thousands" has occurred among the riverine population on the Yangtze Kiang owing to the river rising 16 feet above its normal level and overflowing its banks. In South China the West River has likewise risen in flood and caused much disaster among the people in its neighbourhood.

Peking, August 9th.

Obitnary.

JOHN MILSOM RHODES, M.D. BRUX., L.R.C.P., L.R.C.S. EDIN., J.P.

WE much regret to announce the death of Dr. John Milsom Rhodes, which occurred at his residence at Didsbury, Manchester, on Saturday last, Sept. 25th, in very sad circumstances.

Dr. Rhodes, who was an alderman and a justice of the peace for Lancashire, was one of the best known practitioners in the district, and outside it his name is familiar to all medical men as an ardent supporter of Poor-law reform and chairman of the Central Committee of Poor-law Conferences. He was the author of pamphlets upon pauperism generally and upon pauper lunatics; he wrote a report upon the treatment of the feeble-minded, the insane, and the epileptic by colonies or in institutions founded upon the procedure in the United States; and in our own columns and those of several of our scientific and professional contemporaries he gave voice to clear views on many points in sociology and psychology where knowledge gained as a practitioner enabled him to speak with definiteness. His work on the Central Committee of Poor-law Conferences, as well as his vigorous speeches and writings, influenced legislation on more than one occasion. For example, his pamphlet dealing with workhouse dietaries stirred the Local Government Board to make a departmental inquiry and inspired the Board to remove many of the abuses to which he called attention; and similarly the Report of the Royal Commission on the Deaf and Blind adopted recommendations which he had formulated at a Poor-law con-The medical world has lost in him a vigorous supporter of professional rights.

Dr. Rhodes had suffered for some time from symptoms of heart disease, and it appears that having a hard day's work before him he gave himself a dose of strychnine which, though not unusually large, unfortunately proved fatal. We sympathise with his many friends in their grief at this terrible misadventure and at the abrupt closing of a strenuous and

useful career.

HUBERT ELWYN JONES BISS, M.A., M.D. CANTAB., L.R.C.P. LOND., M.R.C.S. ENG., D.P.H. EDIN. & GLASG.

Hubert Elwyn Jones Biss, the second son of Dr. Cecil Yates Biss, late physician to the Middlesex and Brompton Hospitals, was born in 1872 and received his professional education at King's College, Cambridge, and the Middlesex Hospital. He took his B.A. in the Natural Science Tripos in 1892; his M.A. and M.B., B.C., as well as his college diplomas, in 1896; and his doctorate in 1901. In 1897 he became a house physician at the Brompton Chest Hospital and, shortly after the expiration of his term of office, was chosen to be the immediate medical attendant of the late Mr. Gladstone. In this capacity he resided with his illustrious patient at Hawarden and elsewhere, for some six months, until the end. With what ability and tact he gave his services the continued appreciation and gratitude of the statesman's family well testified. After some time spent in travel Dr. Biss was appointed assistant

strongly attracted to the State relationships of medical science, and took the D.P.H. of Edinburgh and Glasgow. At this time, too, he contributed several papers to the current literature of epidemiology. One paper in particular, that on the Borderlands of Scarlet Fever and Diphtheria, originally published in THE LANCET, is of very considerable importance, and well exemplifies the author's broad and philosophic grasp of his subject.

On his marriage in 1903 Dr. Biss relinquished the service of the Metropolitan Asylums Board, and for a while settled in practice at Eastbourne, continuing, however, his literary work and, in particular as assistant editor of the Medical Press and Circular, contributing valuable articles of public as well as professional interest. But opportunities for other work drew him back to London, and during the last few years he had rapidly acquired both practice and reputation as an expert in assurance and medico-legal work. For this branch of practice Dr. Biss was peculiarly fitted; he had read and thought much on the subjects which he was bent on mastering, and in the courts his wide information and readiness of mind enabled him to hold his own with temper and confidence. He was elected to the council of the Medico-Legal Society, and he was to have read an important paper at the first meeting of the session now about to begin. But attacks of pain, borne bravely and almost silently, became more and more frequent, and were, without doubt aggravated by the rapidly increasing pressure of professional engagements. Early in September he was advised to enter a nursing home at Eastbourne for rest and dietetic treatment. His condition soon became increasingly grave : severe intestinal hæmorrhage occurred, probably from a duodenal ulcer, and despite the devoted care of Dr. A. Harper and other friends the end came, after days of unconsciousness, on Sept. 20th. He was laid to rest at Eastbourne four days later.

Hubert Biss was a man of unusual ability and great ersonal charm and distinction. He deserved success his friends, not least for the sake of the widow and little son, will feel it one of life's bitter ironies that death should have claimed him at this moment, happy as a husband and father, full of eagerness and plans for the future, absorbed in the work which delighted him, and apparently secure in the enjoyment and promise of those things he most desired.

DEATHS OF EMINENT FOREIGN MEDICAL MEN.-The deaths of the following eminent foreign medical men are announced: -Dr. Louis Katz, titular professor of otology in Berlin, author of a microphotographic atlas of the normal and pathological anatomy of the ear and also of a stereoscopic atlas of the ear. He was 61 years of age.—Dr. Léon Hendrix of the Brussels Polyclinic, who was considered the chief authority on children's diseases in Belgium.-Dr. E. L. Marechal, formerly lecturer on hygiene and forensic medicine in the Alabama Medical College, Mobile.

Medical News.

Foreign University Intelligence .-Albany Medical College: Dr. James W. Wiltse has been appointed Lecturer on Dermatology and on Otology.—
Baltimore (University of Maryland): Dr. Irving J. Spear has been appointed Professor of Neurology and Psychiatry.—
Berlin: Dr. Hermann Steudel of Heidelberg has been appointed Extraordinary Professor of Physiology.— Benn. appointed Extraordinary Professor of Physiology.—Benn: Dr. Wilhelm Reis, privat-docent of Ophthalmology, has been granted the title of Professor. - Breslau: Dr. Karl Bruck has been recognised as privat-docent of Dermatology. - Chicago (Rush Medical College): Dr. Anton J. Carlson has been promoted to the chair of Physiology. - Erlangen: Dr. Karl Kleist has been recognised as privat-docent of Mental Diseases.—Florence: Dr. Ottorino Rossi of Pavia has been recognised as privat-docent of Neurology and Psychiatry.—
Innsbruck: Dr. O. Nebesky has been recognised as privat-docent of Midwifery and Gynecology.—Kiel: Dr. Goeppert has been appointed Extraordinary Professor of Children's Diseases in succession to Professor Salge, who is going to Freiburg.—Königsberg: Dr. Paul Stenger, medical officer at the Park and, later, at the Grove Fever privat-docent of Otology, has been promoted to an Extra-Hospitals. During the five years thus spent he became ordinary Professorship.—Naples: Dr. Egidio Maturi has been

recognised as privat-docent of Medical Hydrology.—Prague (German University): The title of Extraordinary Professor has been granted to Dr. Otmar Völker, privat-docent of Anatomy; Dr. Jaroslaw Bukovsky, privat-docent of Dermatology; and Dr. G. Chalupecky, privat-docent of Ophthalmology. Dr. A. Schelb has been recognised as privat-docent of Midwifery and Gynæcology, and Dr. L. Moll as privat-docent of Children's Diseases.—Rome: Dr. G. Mingazzini, Extraordinary Professor of Neurology, has been promoted to the Ordinary Professorship.—Vienna: Dr. Fredrich Dimmer of Gratz has been offered the chair of Ophthalmology together with the Directorship of the First Ophthalmic Clinic in succession to the late Professor Schnabel. Dr. Emil Glas has been recognised as privat-docent of Laryngology and Rhinology.—Yale: Dr. Wilbur Tileston has been appointed Assistant Professor of Medicine.

LITERARY INTELLIGENCE.—The Medical Directory for 1910 is now in preparation and will contain an interesting new feature—a descriptive list of British health resorts, which should prove to be of great value to medical men in giving advice to their patients as to suitable places for change of air. This list has been compiled by Mr. Norman Hay Forbes of Church Stretton. Messrs. J. and A. Churchill can still receive information for this volume. The same firm published last week the eleventh revised edition of Dr. Hale White's popular "Handbook of Materia Medica."—Messrs. W. B. Saunders Company announce that they have in the press and will publish shortly a new work on Malaria by Dr. William H. Deaderick, based on recent investigations. The book will be illustrated by a number of original pictures.

THE LONDON HOSPITAL MEDICAL COLLEGE (UNIVERSITY OF LONDON).—The following entrance scholarships have been awarded: Price Entrance Scholarship in Science, value £120, Mr. J. Bostock; Entrance Science Scholarships, value £60, Mr. A. G. Winter, value £35, Mr. R. J. M. Love; Epsom Scholarship, value £126, Mr. H. G. Winter; Price Scholarship in Anatomy and Physiology (University Scholarship), value £60, Mr. J. R. Marrack (St. John's College, Cambridge).—The "Schorstein" lecture on Syphilis and Aneurysm will be delivered on Friday, Oct. 15th, at 4.30 P.M., by Dr. William Osler, Regius professor of medicine in the University of Oxford. At 4 o'clock the new laboratories for physiology, chemistry, and physics will be formally opened by Professor Osler. The whole of the hospital and college will be open for inspection during the afternoon. Members of the profession will be admitted on presentation of their cards.

CALEDONIAN MEDICAL SOCIETY.—The members of the Caledonian Medical Society, who held their annual meeting last year in Edinburgh, assembled at Lancaster on Sept. 17th for this year's gathering, spending the following day in excursions and sight-seeing. The members of the society are spread throughout the world and the annual reunion is the bond which draws them together. They are all University men and a condition of membership is that they shall have Highland blood in their veins. The reunions are held alternately in Scotland and England. Of the three medical students who founded the society 30 years ago two are still alive. One is Dr. S. R. Macphail, Rowditch, Derby, the secretary and treasurer; and the other is Dr. W. A. Macnaughton of Stonehaven. The first-named has the distinction of having attended every annual meeting. Amongst those present at the Lancaster meetings this year were Sir William Sinclair, Dr. Greenlees, five members from Scotland, two members from South Africa, and one from Nigeria. The annual meeting was held under the presidency of Dr. D. Blair, who explained that the society had definite aims, of which its devotion to Gaelic medical literature was a special feature. They had just received a translation of a valuable old Celtic medical manuscript. Most of the Gaelic manuscripts which he had read had been translated by members of the society or by scholars endowed by the society. During the meeting speeches were made in which reference was made to the work of the late Sir Richard Owen and Sir William Turner, both distinguished Lancastrians. Major Burke spoke of the Army Medical Corps as providing a fine field for young medical men, offering them unrivalled opportunities of seeing the world, of engaging in scientific research, and of attaining a status unattainable by most general practitioners.

THE WEST LONDON POST-GRADUATE COLLEGE.—
The title of Professor Theodor Schott's address, which is to be delivered at the West London Hospital on Oct. 11th at 5 P.M., will be "A Renewed Research on the Subject of Acute Overstraining of the Heart."

Insanitary Overcrowding.—A man was summoned at Mansfield last week by the Corporation for allowing seven people, between the ages of six and 20 years, to sleep in one room in his house. He was ordered to abate the nuisance and pay the costs of the summons.

DONATIONS AND BEQUESTS. — Mr. Francis Tagart has given £1000 to the Royal Infirmary, Bristol, towards defraying a debt of £3500.—Mr. J. Bland-Sutton has given £1000 towards the fund which is being raised for the purchase of an athletic ground for the Middlesex Hospital Medical School.

UNIVERSITY COLLEGE, LONDON.—In connexion with the opening of the session of the Faculty of Science and the Faculty of Medical Sciences at University College, London, Professor Sir William Ramsay will give a public introductory lecture on "Radium Emanation; One of the Argon Lines of Gases," on Monday, Oct. 4th, at 9 A.M.; and Professor H. R. Kenwood will give a similar lecture on "What Hygiene demands of School Teachers," on Wednesday, Oct. 6th, at 7 P.M.

CHARING CROSS HOSPITAL MEDICAL SCHOOL.—The following entrance scholarships have been awarded at this school:—The Epsom scholarship (60 guineas) to Mr. Duncan W. Pailthorpe, the Livingstone scholarship (75 guineas) to Mr. Francis J. Hallinan, and the Huxley scholarship (50 guineas) to Mr. David B. S. Jones. An entrance scholarship has also been awarded to Mr. Harold W. Williamson (30 guineas); a universities scholarship of 50 guineas to Mr. I. Milton Davies, and a universities exhibition of 20 guineas to Mr. Abel Evans, both of the London University.

St. George's Hospital Medical School.—A course of six lectures on Public Health will be given in the Medical School of St. George's Hospital by Mr. F. E. Fremantle, Edward Jenner lecturer, on Tuesdays, Nov. 2nd, 9th, 16th, 23rd, and 30th, and Dec. 7th, at 4 o'clock. The following subjects will be discussed: (1) The Declining Birth-rate; (2) Vital Statistics; (3) Infant Health; (4) School Health; (5) Isolation Hospitals; and (6) Housing and Town Planning. These lectures are open to those interested in public health, a fee of half a guinea being charged for the course. Application for tickets of admission should be made to Mr. S. A. Williamson, clerk to the Dear, St. George's Hospital Medical School, S.W.

PRESENTATION TO A MEDICAL MAYOR.—At Leicester on Tuesday evening last presentations were made to Mr. Charles Lakin, L.R.C.P. Edin., L.S.A., mayor of Leicester this year, and to Dr. Robert Wallace Wesley Henry. The presentations were from the blind people of the town and the council of the Wycliffe Society for Helping the Blind, and were in recognition of many years of service by Mr. Lakin as honorary physician and Dr. Henry as honorary ophthalmic surgeon to that institution. At Tuesday's meeting of the Leicester town council a special committee was appointed to make the necessary arrangements for a banquet to the retiring mayor on the conclusion of his year of office on Nov. 1st.

MEDICAL SICKNESS AND ACCIDENT SOCIETY.—The usual monthly meeting of the executive committee of the Medical Sickness, Annuity, and Life Assurance Society was held on Sept. 24th. There was present: Mr. J. Brindley James (chairman), Dr. M. G. Biggs, Dr. H. A. Sansom, Dr. J. W. Hunt, Dr. F. J. Allan, Mr. W. Thomas (Birmingham), Dr. F. C. Martley, Dr. Frederick S. Palmer, Dr. W. G. Dickinson, Dr. W. A. Dingle, Mr. F. S. Edwards, Dr. W. Knowsley Sibley, Mr. Edward Bartlett, and Dr. J. B. Ball. The records show that the business of the society is still growing in a satisfactory manner. Every year shows an increase in the number of members and the amount of the invested reserve, while the amount paid away in sickness claims does not exceed what is expected and provided for in the tables of contributions. The society has no agents and pays no commission, while the funds earn a considerable amount more interest than is assumed in the valuation of the

business. The substantial surplus thus produced allows of the payment of a handsome bonus to those members who reach the age of 65 years. Prospectuses and all further particulars can be obtained on application to Mr. F. Addiscott, secretary, Medical Sickness and Accident Society, 33, Chancery-lane, London, W.C.

THE MEDICO-PSYCHOLOGICAL ASSOCIATION.—The autumn meeting of the South-Eastern division of this association will be held, by the courtesy of Dr. J. O. Adams and Mr. G. H. Johnston, at Brooke House, Upper Clapton, N.E., on Wednesday next, Oct. 6th. The proceedings will commence at noon, when members will inspect the house and grounds. After luncheon the general meeting will be held and the following communications read: By Dr. F. W. Edridge-Green, the Theory of Vision and Colour Perception (this paper will be illustrated with coloured lantern slides); and by Dr. T. Duncan Greenlees, Lunacy Matters in Cape Colony. The members will dine together after the meeting at the Café Monico, Piccadilly-circus, W., at 6.45 P.M.

Parliamentary Intelligence.

NOTES ON CURRENT TOPICS.

The Housing and Town Planning Bill.

THE Housing and Town Planning Bill has undergone drastic altera tion in committee of the House of Lords. The amendments introduced into the Housing part are numerous, but the Town Planning part has been completely transformed. In fact, so great is the deviation from the text of the Bill as it left the House of Commons that it is understood that the Government is taking into its consideration the advisability of dropping the part relating to Town Planning. In the Bill as it reached the Lords very extensive powers in regard to town planning schemes were vested in the Local Government Board. The attitude of the majority of peers was that those powers were quite beyond what it was desirable to confer on an executive department. Accordingly a scheme of procedure by provisional order in Parliament was substituted in cases where objection was taken to a scheme. The view of the Government is that this procedure is so costly that it will defeat the objects of the Bill. In the clause relating to the appointment of county medical officers of health, the peers, against the deliberate advice of the Government, insisted on two amendments. They struck out the provision that the Local Government Board might by order prescribe the duties of medical officers of health appointed by a county council. They also removed the subsection which made a county medical officer removeable only with the consent of the Local Government Board. Both the Earl of CREWE, who leads the Government in the Rouse of Lords, and Earl BEAUCHAMP, who has had charge of the Bill, protested against thes amendments.

Local Education Authorities (Medical Treatment) Bill.

The Local Education Authorities (Medical Treatment) Bill has been read a third time and passed by the House of Lords. Its object is to provide for the recovery by local education authorities of costs for medical treatment of children attending public elementary schools in England and Wales.

The Motor-cars of Medical Men.

The clauses of the Finance Bill dealing with the taxation of motorcars and motor spirit have been passed by the House of Commons. Clause 65 lays down certain conditions which are to accompany exemptions and allowances in respect of the duty on motor spirit, but the concession which the Chancellor of the Exchequer promised to medical men will be embodied in one of the schedules which have still to be considered. Clause 66, which imposes a duty on licences for motor-cars, contains a subsection relieving medical men of half its amount. It runs thus: "It a duly qualified medical practitioner proves to the satisfaction of the Commissioners or council by whom the licence is granted that any motor-car kept by him is kept for the purpose of his profession, he shall be entitled to an allowance in respect of the duty payable under this section on the car equal to half the amount of duty so payable."

Metropolitan Ambulances Bi'l.

The Metropolitan Ambulances Bill has been read a third time and passed by the House of Lords.

HOUSE OF LORDS.

THURSDAY, SEPT. 23RD.

County Medical Officers of Health.

During the discussions on the Housing, Town Planning, &c., Bill in committee the House considered Part III. which relates to county medical officers, county public health and housing committees, &c. Clause 68 runs as follows:—

(1) Every county council shall appoint a medical officer of health under section seventeen of the Local Government Act, 1888.

(2) The Local Government Board may by order prescribe the duties of medical officers of health appointed by a county council under section seventeen of the Local Government Act, 1888, whether before or after the passing of this Act.

(3) The power of county councils and district councils under the said section to make arrangements with respect to medical officers of health shall cease, without prejudice to any arrangement made previously to the date of the passing of this Act.

(4) The medical officer of health of a county shall, for the purposes of his duties have the same powers of entry on premises as are

of his duties, have the same powers of entry on premises as are conferred on a medical officer of health of a district by or under any enactment.

(5) A medical officer of health of a county shall be removeable by the county council with the consent of the Local Government Board and not otherwise.

(6) A medical officer of health of a county shall not be appointed for a

(6) A medical officer of health of a county shall not be appointed for a limited period only. Provided that the county council may, with the sanction of the Local Government Board, make any temporary arrangement for the performance of all or any of the duties of the medical officer of health of the county, and any person appointed by virtue of any such arrangement to perform those duties or any of them shall, subject to the terms of his appointment, have all the powers, duties, and liabilities of the medical officer of health of the county.
(7) A medical officer of health appointed under the said section as amended by this section shall not engage in private practice, and shall

amended by this section shall not engage in private practice, and shall not hold any other public appointment without the express written consent of the Local Government Board.

(?) A medical officer of health appointed under the said section as amended by this section shall not engage in private practice, and shall not hold any other public appointment without the express written consent of the Local Government Board.

Lord Beller, as an amendment, moved to omit Subsection (2) which gives the Local Government Board power to prescribe the duties of county medical officers of health. Speaking for the County Councils' Association, he said that the proposal in the Bill would interfere to a large extent with the county councils carrying out their duties in an efficient manner. He did not think there was any case for direct interference of this sort by a Government department, and it was entirely contrary to the whole system of local government that the duties of medical officers of health should be laid down and prescribed by the Local Government Board. He thought that the medical officers of health of counties were in a sufficiently independent position to be able to withstand any improper pressure. If their duties were to be prescribed by the Local Government Board the medical officer would feel that he was more under the authority of the department than of the county council. That, he considered, night have unfortunate results.

Lord CLIFFORD of CHUDLEIGH considered that the subsection was in the nature of an insult to county councils. Surely they could be trusted without the Local Government Board taking upon itself the power to give direct orders to its servants.

Karl Beauchamy (who was in charge of the Bill) replied that His Majeety's Government attached a very real importance to this subsection, which the two noble lords were anxious to omit from the Bill. There was no intention on the part of the Local Government Board to do anything to interfere with the dignity of county councils. All the county boroughs had their medical officers of health of counties should be defined. Uniformity was of importance in such matters as the goth of the case of county councils not so progressive as

Lord Belper said, with regard to the remark of Earl Beauchamp about the medical officers of county boroughs, that the boroughs were sanitary authorities. The county councils were merely supervising

sanitary authorities. The county councils were merely supervising bodies.

The Earl of Crews said that he was sorry that the county councils had taken up a hostile attitude to the subsection. There could be no intention of offering any insult to them. The object of the Government's proposal was to secure a minimum standard of efficiency in the medical officer. Even the most devoted admirer of the county councils would admit that the councils themselves were not equally independent and efficient, and those whom they appointed possessed varying degrees of efficiency. Noble lords opposite, after taking the view which they had exhibited throughout all the discussion of the Bill with regard to the policy of the Local Government Board, were not likely to be convinced by anything which he could say on this subject. The suggestion made by Viscount St. Aldwyn would narrow the operations of the clause and would apply only to the Bill. He regretted that the Government was not able to give way on this point and he did not know whether it was any use to discuss the matter further. The amendment was then carried without a division and Subsection (2) omitted.

section (2) omitted.

section (2) omitted.

Lord Belfer moved as an amendment to leave out Subsection (5), which provided that the consent of the Local Government Board should be necessary for the removal from office of a county medical officer of health. He expressed surprise at the language used by the noble lord in charge of the Bill. In those counties where medical officers of health had been appointed they were men of high integrity

and it would be an insult to suggest that their action would be influenced by unworthy considerations. So far as he knew of the atmosphere of county councils it was entirely out of the question to suggest that a medical officer would be pensilsed for his actions. It was almost unthinkable that if pressure were attempted to be brought to bear upon a medical officer of health by a member, it would be tolerated. There might have been such a case, but he had never known of it.

to bear upon a medical officer of health by a member, it would be tolerated. There might have been such a case, but he had never known of it.

Earl Beaughamp said that it was with the same acute sense of helplessness that he now mentioned that His Majesty's Government did attach great importance to this subsection. One of the main objects of His Majesty's Government was to do its utmost to raise the status of the medical officers of health throughout the country. Surely everyone was anxious that the country medical officer of health should be the best man that could be got. This and similar proposals to raise their position had been the desire of social reformers for many years. He did not think that the subsection went too far, and he made an appeal to their lordships to allow it to remain.

The Marquis of Landowne thought that their lordships should do nothing to belittle the authority of the county councils. Until lately it had been the policy to strengthen those great bodies, and he regretted to see a different tendency now. It was essential that the rolations of a medical officer and his council should be most cordial, but these relations were not likely to be improved if the council knew that his allegiance was not due to it but to a public department in London. He desired to do nothing which might impair the authority of the county council in a matter of this sort.

The Earl of Kimberrey remarked that he was not afraid of the Local Government Board in this matter. His experience was that the duties of a county medical officer were very slight. He would like to see more power given to him and to have it defined in a definite way. Eventually he must become a great officer, dealing with the water-supply and other matters. Whilst he did not think that it would be a good thing for the county medical officer of health to undertake the medical inspection of shool children, yet he might supervise, the work, and he might also be over the district medical officer, dealing with the ware, and he might also be over t

Lord MonkBartron proposed the first of a series of amendments to Subsection (7) so as to make it read "a medical officer of health appointed under the said section as amended by this section shall not appointed under the said section as amended by this section shall not engage in general medical practice without the express written consent of the Local Government Board, without prejudice to any arrangement made previously to the date of the passing of this Act in the case of a medical officer already appointed under Section 17 of the Local Government Act of 1883." The noble lord, in explaining the purpose of his amendments, said that he took it that these medical officers should not be excluded from lectureships in hospitals and from examining in amiversities, and from doing those things which the Local Government Board allowed its own officers to do.

Rarl BEAUCHAMP said that the Government did not see its way to accept the amendment. It would allow the county medical officer to engage in general consulting practice. That might take up a great deal of his time and take him away from the work of the county. He further pointed out to the noble lord that by the subsection the Local Government Board was empowered to give its consent to a county medical officer holding other public appointments.

Lord Monk Bertton did not press his amendments.

The clause as amended by the omission of Subsections (2) and (5) was agreed to.

agreed to.

HOUSE OF COMMONS.

THURSDAY, SEPT. 23nd.

Soldiers' Teeth.

Soldiers' Tecth.

Mr. John Ward asked the Secretary of State for War whether, in view of the fact that many recruits for the regulararmy, otherwise qualified, were rejected because of defective teeth, means would be devised to rectify this falling, and so make considerable reduction in the proportion of rejections.—Mr. Haldden amered: Whenever in the opinion of a recruiting medical officer dental treatment will render a recruit efficient, the necessary treatment is now given, provided its cost does not exceed £1.

not exceed £1.

Mr. J. WARD: Is that really the estimate of the value of a recruit-

a sovereign?

Mr. HALDANE: No, it is not; but we do not supply false teeth for 50,000 troops.

Mr. A. LYNOH: Will provision be made for the proper care of soldiers teeth as part of their regular daily routine?

Mr. HALDANE: That is not a question which arises out of the one which I answered. The right honourable gentleman added in reply to further supplementary questions: For the last two years there has been a very considerable improvement in the teeth.

Army Recruits.

In reply to Mr. SUMMERBEIL, Mr. HALDANE said that in the period from July 1st, 1908, to June 30th, 1909, the total number of men who presented themselves for enlistment in the army was 59,686 and the total number found lit to serve was 43,134.

Hospitals and the Spirit Duties.

In the discussion on clause 61 of the Finance Bill, which imposes additional customs and excise duties on spirits, reference was made to the effect it was likely to have on the price of medicines and on the

maintenance cost of hospitals.

Sir William Bull, as an amendment, moved to omit the subsection which increased the duties proportionately on certain articles in which spirits were contained or in the manufacture of which they were used. This, he said, raised the question of taxing medical spirits. This was not a question of luxury but of necessity. When people were

ill spirits of this kind were ordered and they were bound to take them. This was a very heavy tax on people who were ill able to afford it. A large number of hospitals were struggling under great difficulties and the increase of the cost involved by this taxation was estimated for some of them to amount to £2900 or £3000 a year. He had been in communication with several large chemists throughout the country, and he had just had a letter from one who stated that he did not trouble about the tax because he simply intended to put it on to the consumer. He had had a letter from another who said that his bill in connexion with these spirits would be over £3500 a year. Taking the London hospitals alone, he understood the tax would amount to over £30,000. It was bound to be extremely unpopular amongst the poorer classes. Even a poor man who had to have a tooth extracted under gas would probably have to pay more fees on account of the tax.

Mr. HODHOUSE: (Secretary to the Treasury) said that as he understood it the proposal was to leave unaltered duty on certain articles to which the amendment related. That would be a very difficult thing to do. The late Lord Ritchie when Chancellor of the Exchequer brought in a Bill in 1903 to try to do something of the sort. That Bill failed. The time held by the honourable gentlemen opposite were for some little time held by the Pharmaceutical Society, which sent a deputation to the Chancellor of the Exchequer. They heard what was to be said by the Board of Customs and Excise on the question, and they went away satisfied that the proposals embodied in this amendment were impracticable for this reason. If the Treasury gave spirits duty free to chemists and hospitals, they could not subsequently control the disposal of the spirits by the person who was cutified to obtain them duty free. He could distill the spirits out of the particular articles mentioned in the schedule, and it could not be said whether they were used in a hospital or elsewhere. It would be impossible to asy whether

The Government could not accept the amendment.

Mr. AUSTEN CHAMBERIAIN remarked that without access to official information be could not say whether it would be possible for the excise to take sufficient security in the case of chemists. He only hoped that the Government had seriously considered the question before they decided that it was impossible to make the distinction. However, he would say that it was one more reason against adding to the very heavy spirit duties. The tax was working out as a very heavy spirit duties. The tax was working out as a very heavy great extent. It would fall very heavily upon hospitals, dispensaries, and other institutions of that kind.

Mr. LYULPH STANLEY and Mr. FELL also supported the appeal for exceptional treatment for medicinal spirits. The amendment was rejected by 159 votes to 84.

The Ailments of Female Telegraph Operators.

The Allments of Female Telegraph Operators.

Mr. J. P. FARRELL asked the Postmaster-General whether he was aware that muscular paralysis of the arm had become prevalent in the female branch of the telegraph service by reason of the long hours of duty imposed, especially in big offices; whether he was aware that hysteria, nervous breakdown, and other symptoms followed, and whether an alternation of duties would be devised whereby these maladies could be obviated and greatly prevented. Mr. Buxnox wrote in reply: I should be glad if the honourable Member would furnish me with particulars of any case of paralysis of which he has cognisance, and I will at once inquire into it. I am not aware of any prevalence of the allments referred to in the question.

MONDAY, SEPT. 27TH.

Medical Services in India.

Mr. HAZLETON asked the Under Secretary of State for India whether Mr. Hazleton asked the Under Secretary of State for India whether the positions of military assistant surgeons in India were open to Indians; whether the salaries of these positions were higher than those of civil assistant surgeons who were mainly Indians; and whether it was proposed to remove the disqualification in the way of competent Indians entering all ranks of the medical service of their country.—The MASTER OF ELHBANK replied (by written answer): The answer to the first question is in the negative, military assistant surgeons being regarded primarily for service in European military hospitals. The answer to the second question is in the affirmative, but the difference in rates of pay is not very considerable, being confined to the highest graded. The Secretary of State will consult the Government of India as to the advisability of some revision to the constitution of this branch of their medical service. medical service.

TUESDAY, SEPT. 28TH.

Tubercle of the Lung in the Army.

Mr. Summerbell miked the Secretary of State for War whether be Mr. Summerbell saked the Secretary of State for War whether be could state the number of soldiers that have been discharged from the army during the ten years ending 1903 suffering from tubercle of the lung, and the precautions taken by his department to prevent the spreading of the disease.—Mr. Haldane replied: The number of men so discharged was as follows:—1899, 224; 1900, 328; 1901, 350; 1902, 334; 1903, 301; 1904, 440; 1905, 333; 1906, 400; 1907, 304; and 1908, 272. While in hospital patients suffering from tubercle of the lung are generally kept apart from other patients and treated generally as case of infectious disease. On discharge, a notification is sent to the medical officer of health in the town or district where the man proposes to reside. The treatment in military hospitals (the right honourable gentleman continued in answer to further questions) is confined to temporary retention of a few men as free patients owing to unfitness to travel. The cost of maintenance in these cases in homes is not provided from army funds. No special money grant is made to soldiers discharged from the army suffering from tubercle of the lung.

The Vaccination Act, 1907.

The Vaccination Act, 1867.

The Vaccination Act, 1807.

Mr. Pointer asked the President of the Local Government Board whether he would cause inquiry to be made into the practice of vaccination to ascertain whether the lymph now used had its origin in, or was in any way connected with, variolous matter; and whether, should his inquiries go to show that variolous matter was the origin of the present-day lymph, he would institute proceedings under Section 32 of the Vaccination Act of 1867 against persons using such lymph.—BURNS answered: Section 32 of the Vaccination Act, 1867, renders it an offence to produce, or attempt to produce, small-pox in any person by inoculation with variolous matter or by any other means. Most of the lymph used in cases of primary vaccination is that supplied from the

Government lymph establishment. That lymph does not produce, and is not used to produce, small-pox, and persons using it do not come within the section referred to. There is no reason to doubt that the same observations apply with regard to other lymph in use in this country. There does not appear to me to be any need for inquiry on country. T

Medical Relief and Old-Age Pensioners.

Answering Mr. CECIL HARMSWORTH, Mr. BURNS said: If an old-age pensioner applies to the guardians for medical relief it is their duty to consider whether any such relief should be given to him, and, if so, in what form. The receipt of any medical or surgical assistance by or on the recommendation of a medical officer would not disquality the pensioner from the receipt of his pension.

The Medical Treatment of Suffragist Prisoners.

The Medical Treatment of Suffragist Prisoners.

Mr. KERHARDE asked the Secretary of State for the Home Department whether he had any official information concerning the state of health of the nine women suffrage prisoners in Winson Green Gaol, Birmingham; how many of them were being subjected to hospital treatment; and whether he could say under what prison rule or regulation one of the prisoners had had food pumped down her throat against her will.—Mr. MASTERMAN (who replied for Mr. Gladstone) said: Yes, Sir, the Secretary of State has received a report this morning from the Governor of Birmingham prison to the effect that six of the suffragist prisoners are still under special medical treatment for self-starvation, and that in consequence of this treatment the condition of health of these prisoners shows progressive improvement. No prison rule or regulation deals specifically with this subject. It is the duty of the prison authorities to take such steps as are necessary to prevent prisoners from committing suicide or doing themselves personal migury. If they allowed any of their prisoners to cause their own death by starvation they would incur the greatest censure, if, indeed, they did not lay themselves open to criminal proceedings. In previous similar cases of this kind the prison authorities have always recognised this duty.

Mr. Weight Hanney of the the feet that else of these women are still. this duty.

Mr. Keir Hardie: Is it the fact that six of these women are still being fed by means of the stomach pump?—Mr. Masterman: The information which I have received shows that there are various means of persuading these women to take nourishment, and only in the last resort is the ordinary hospital instrument used. I believe it has been used only in three cases.

CANTERBURY, KENT AND CANTERBURY HospITAL.—House Physician, unmarried. Salary £70 per annum, with board, lodging, and

washing.
CENTRAL LONDON THROAT AND BAR HOSPITAL, Gray'S Inn-road, W.C.

UENTRAL LONDON THROAT AND HAR HOSPITAL, Gray's Inn-road, W.C.

—Honorary Registrar.

CHESTER, CITY OF.—Assistant Medical Officer of Health. Salary £250
per annum.

COLCHESTER, ESSEX COUNTY HOSPITAL.—House Physician, also House
Surgeon. Salarles £30 per annum, with board, residence, and
washing.

DERBY. COUNTY ROBOURY

DERBY, COUNTY BOROUGH.—Assistant Medical Officer of Health.

DERBY, COUNTY BOROUGH.—Assistant Medical Officer of Health.

Salary £120 per annum, with board and lodging.

DUDLEY, GUEST HOSPITAL.—Assistant House Surgeon. Salary £75 per annum, with residence, board, and washin g.

EAST LONDON HOSPITAL FOR CHILDREN AND DISPENSARY FOR WOMEN, Shadwell, E.—Surgeon, also Assistant Surgeon. Also Second Medical Officer to the Casualty Department for six months. Salary strate of £40 per annum, with luncheon and tea.

EDINBURGH SCHOOL BOARD.—Two Assistant Medical Officers (one male, one female). Salaries £250 and £200 per annum.

FARRINGDON GENERAL DISPENSARY AND LYING-IN CHARITY, 17, Bartlett's Buildings, Holborn-circus, E.C.—Resident Medical Officer. Salary £100 per annum, with momes. &c.

Bartlett & Billionings, noncorn-circus, r. C.—Resident mesical Omeer.
Salary £100 per annum, with rooms, &c.
Greenock Infirmary.—Assistant House Surgeon. Salary £40 per
annum, with board and residence.
Halifax Union Poor-Law Hospital, Salterhebble.—Resident Medical
Officer. Salary £130 per annum, with spartments, rations, and

Washing.

Hampstead General Hospital.—House Physician, also House Surgeon, both for six months. Salaries at rate of £70 per annum, with board and residence.

HERTFORD COUNTY HOSPITAL.—Resident House Surgeon, unmarried.
Salary at rate of £100 per annum, with board, washing, and apartments.

Hospital for Sick Children, Great Ormond-street, London, W.C.—
House Surgeon, unmarried, for six months. Salary £30, with
board and residence. Also Honorary Anasthetist.

Ipswich, East Suffolk and Ipswich Hospital.—Third House
Surgeon. Salary £55 per annum, with board, lodging, and washing.

Kettering and District General. Hospital.—Resident Medical Salary £100 per annum, with board, resi-Officer, undence, &c.

dence, ac.
King Edward VII. Sanatorium, Midhurst, Sussex.—Junior Assistant
Medical Officer. Salary £100 per annum, with board, lodging, and attendance.

LEEDS. HOSPITAL FOR WOMEN AND CHILDREN.-Two House Surgeons.

LEEDS, HOSPITAL FOR WOMEN AND CHILDREN.—I wo frouse Surgeons. Salary at rate of 250 per annum, with board.

Lincoln Mental Hospital, The Lawn, Lincoln.—Assistant Medical Officer, unmarried. Salary £150 per annum, board, &c.

LONDON HOSPITAL, Whitechapel, E.—Surgeon, Assistant Surgeon, Medical Officer in charge of the Radiographic Department, and two

Medical Officer in charge of the Radiographic Department, and two Assistant Anaschetists

MOUNT VERNON HOSPITAL FOR CONSUMPTION AND DISEASES OF THE CHEST, Hampstead and Northwood, Middlesex.—Senior and Junior Resident Medical Officers. Salary of former £100, and of latter £50 per annum, with board and residence. Also Assistant Physician.

NewPort AND Monmouthshire Hospital.—House Physician. Salary £80 per annum, with board, residence, and laundry.

Norwich, Norfolk and Norwich Hospital.—House Physician, unmarried. Salary £20 per annum, with board, lodging, and

washing.

NOTTINGHAM GENERAL DISPENSARY.—Two Assistant Resident Surgeons, unmarried. Salary £160 each, with apartments, attendance, light, and fuel.

ORKNEY, PARISH COUNCIL, PAPA WESTRAY.—Medical Officer and Public Vaccinator. Salary £100 per annum and fees.

PAISLEY, GOVAN DISTRICT ASYLUM, Hawkhead.—Second Assistant Medical Officer. Salary £150 per annum, with rooms, board,

Medical Officer. Salary £150 per annum, with rooms, board, laundry, and attendance.

PRINCE OF WALES'S GENERAL HOSPITAL, Tottenbam, N.—House Surgeon, House Physician, Junior House Surgeon, and Junior House Physician. Salarics of two former £75 per annum, and of two latter £40 per annum, with residence, board, and laundry.

QUEER'S HOSPITAL FOR CHILDREN, Hackney-road, Bethnal Green, E.—House Surgeon for six months. Salary at rate of £50 per annum, with board, residence, and laundry. Also Assistant Resident Medical Officer. Salary £75 per annum, with board, residence, and washing.

washing.
ROTHERHAM HOSPITAL AND DISPENSARY.—Assistant House Surger

Salary £80 per annum, with rooms, board, and washing.

ROYAL HOSPITAL FOR DISEASES OF THE CHEST, City-road, London,

E.C.—Resident Medical Officer for six months. Salary at rate of £120 per annum, with board, lodging, and washing. Also Assistant Physician.

Physician.

ROYAL NATIONAL ORTHOP EDIC HOSPITAL. 234, Great Portland-street,
W.—Resident House Surgeon. Salary £100 per annum, with board,
residence, and washing.

St. GLIES', CAMBERWELL, INFIRMARY AND WORKHOUSE, S.E.—Assistant
Medical Officer for Infirmary and Workhouse, and Assistant Medical
Officer for Infirmary. Salaries £140 and £120 per annum, with
apartments, board, and washing.

apartments, board, and washing.

St. Panoras Infirmary and Workhouse, Panoras-road, N.—Assistant Medical Superintendent and Medical Officer. Salary £135 per annum, with residential allowances.

SHEFFIELD ROYAL INFIRMARY.—Assistant House Physician. Salary £50 per annum, with board and residence.

SOUTH SHIELDS, INGHAM INFIRMARY AND SOUTH SHIELDS AND WESTOE DISPENSARY.—Senior House Surgeon. Salary £100 per annum, with residence, board, and washing.

SOUTH WALES AND MONMOUTHSHIRE UNIVERSITY COLLEGE.—Assistant Lecturer and Demonstrator in Anatomy.

STAFFORD, STAFFORDSHIRE GENERAL INFIRMARY.—Assistant House Surgeon. Salary £82 per annum, with board, residence, and laundry

SURBEY DISPENSARY, Southwark, S.E.—Physician. Salary 50 guineas

BURREY DISPENSARY, SOULDWARK, S.E.—FINSHEIGH. SCHOOL GRAND BOTTAL, TAUNTON AND SOMERSET HOSPITAL, Taunton.—Resident Assistant House Surgeon for six months. Salary at rate of £50 per annum, with board, lodging, and laundry.

TUNERIDGE WELLS GENERAL HOSPITAL.—Junior Resident Medical Officer. Salary £30 per annum.

WANDSWORTH UNION INFIRMARY, St. John's-hill, near Clapham Junction.—Junior Assistant Medical Officer, unmarried, for six months. Salary at rate of £120 per annum, with board, lodging, and washing. and washing.
Weston-super-Mare Hospital.—House Surgeon, unmarried. Salary

£100 per annum, with board and residence.

THE Chief Inspector of Factories, Home Office, London, S.W., gives notice of a vacancy as Certifying Surgeon under the Factory and Workshop Act at Keighley, in the county of York.

Births, Marriages, and Deaths.

Cole,—On Sept. 28th, at 25. Upper Berkeley-street, Portman-square W., the wife of Robert Henry Cole, M.D., of a son.

Corfield.—On Sept. 21st, at Heechwood, Upper Tooting, the wife of Carruthers Corneld, M.R.C.S. Eng., L.R.C.P., L.S.A. Lond., of a

Carruthers Corfield, M.K.C.S. Eng., L.K.C.P., L.S.A. Lond., of a daughter.

LUND.—On Sept. 25th, at Collingham-road, S.W., the wife of Kenneth F. Lund, M.B. Lond., of a daughter.

MANSELL.—On Sept. 25th, at "Crofton," West Hill, Hastings, the wife of H. R. Mansell, M.R.C.S.. of a daughter.

MARTIN.—On Sept. 20th, at Court, Cullompton, Devonshire, the wife of Captain J. F. Martin, R.A.M.C., of a daughter.

MARRIAGES.

ALEXANDEB—ORME.—On Sept. 7th, at Angmering, Sussex, Frederick Hugh Alexander, M.B. Lond., M.R.C.S., L.R.C.P., of Little-hampton, Sussex. to Agnes, youngest daughter of the Rev. J. B. Orme, Rector of Angmering.

CHIDELL—WESTALL—On Sept. 21st, at St. Matthias's Church, Richmond, Surrey, Claude Churchill Chidell, M.B., B.S. Lond., to Ethel Alicia Isabel, youngest daughter of the late William Westall, of Rydal, Worthing.

Bthel Alicia Isabel, youngest daughter of the late William Westall, of Rydal, Worthing.

DINGLE-WHITELIAW.—On August 16th, at St. Michael's, Sandakan, B.N. Borneo, Percival A. Dingle, M.R.C.S., L.R.C.P. Lond., to Norah, widow of Dr. T. Buchanan Whitelaw.

DOUTY—WILLS.—On Sept. 21st, at St. Paul's, Knightsbridge, Edward Henry Douty, M.A., M.D., to Kathleen Mary Hamilton Wills, youngest daughter of the late Sir Frederick Wills, Bart., and Lady Wills.

GEOGHEGAN—PICETHORN.—On Sept. 23rd, at St. Mary's, Hammersmith, Staff-Surgeon Herbert Lyne Geoghegan, M.D., R.N., to Ella, only daughter of the late Inspector-General T. Russell Pickthorn, R.N.

DEATHS.

DEATHS.

ALLEM.—On Sept. 28th, at Scarborough, suddenly, John Edward Allen, M.D., F.R.C.S., B.Sc., of S. Nicholas House, York, aged 58.

BULLEID.—On Sept. 27th, at Connaught-street, Hyde Park, George Bulleid, M.R.C.S., in his 39th year.

COBBIN.—On Sept. 21st, suddenly, at Merivale, Beckenham, Kent, E.R. St. Clair Corbin, M.B. Lond., M.R.C.S. Eng., aged 51 years.

PHILLIPS.—On Sept. 25th, in London, George Richard Turner Phillips, J.P., M.R.C.S., M.S.A.

N.B.—A fee of 5s. is charged for the Insertion of Notices of Births, Marriages, and Deaths.

Rotes, Short Comments, and Answers to Correspondents.

A RELIC OF DIOSCORIDES.

Some 60 years ago a rectangular stone receptacle, apparently for containing manuscripts, was discovered at Alexandria, bearing an inscription reading ΔΙΟΣΚΟΥΡΙΔΗΣ Γ ΤΟΜΟΙ. This coffer has now disappeared, but its correct dimensions were preserved among the papers of the late Mr. C. Harris, British Consul at Alexandria, who noted that it was a "block of granite dug up in 1847 17½ inches long, 15½ wide and deep, whilst the hole carved out of the top for the books was 10 inches by 8, with a depth of 3 inches. This relic is interesting for two reasons—firstly, because it was almost certainly made to preserve one or more works of the famous botanist and medical author, Dioscorides of Anazarba; and secondly, because if this is correct, and if it was made for the great library at Alexandria. it was intended for the new collections of books founded to replace the library destroyed by Cæsar's soldiers. There were some eight or nine authors who were named Dioscorides, one of whom, a writer of epigrams, is said to have lived at Alexandria, but none of them were so celebrated as the Dioscorides of "Materia Medica" fame, and it is more than probable that he is the person whose works are alluded to in the text. The size of the receptacle is just ample to have provided for three rolls of papyrus, which are doubtless indicated by the three "tomol." The "De Materia Medica," however, consisted of five books, but there is no reason why the scribes should not have so engrossed the work that it occupied three codices. Perhaps, however, each papyrus roll bore one complete work of Dioscorides. Many have been attributed to him, and two of these appear to really have been his production. the Περί δηλτηήριων φάριακων and the Περί Ιοδόλων. There is a fourth treatise, a "De Venenis," attributed to Dioscorides. but its contents appear to have been in many cases compiled from Oribasius, as was so much of the work of Paul of Ægina. Plagiarism was an almost universal practice amongst classic medical encyclopædists and the "De Materia Medica" itself of Dioscorides is believed to be mainly derived from the work of the same title by Sextius Niger, of the time of Augustus. In the same way Oribasius is now known to have drawn largely for part of his book upon the "De Venenatis Animalibus" of Philoumenos. Necessarily if some of the contents of the "De Venenis," ascribed to Dioscorides, are derived from Oribasius, who flourished later, the treatise cannot be by the famous author of that name who wrote the "De Materia Madica.

The Dioscorides whose three books were to be protected in the stone receptacle must have been a celebrated writer to have a special coffer to protect particularly valued works, for the coffer was placed at the base of a statue of the author at the entrance to the library or of some medical school. The object of providing this costly and indestructible stone capsa was to prevent any damage to the precious book it guarded. Pliny speaks of "armsria" inserted in the walls of libraries, and a bas-relief found in Germany, probably dating from the second century, shows manuscript rolls lying in square compartments apparently of stone. Moreover, it was a practice in Egypt to keep papyri in stone receptacles. The "Rules" of the early Christian monk Pachomius refer to these, and in the ruins of an old Coptic convent the most ancient copy of the "Coptic Psalter" known was found in a stone coffer. The form of the letters on the coffer gives a clue to the date when they were inscribed, which erudite epigraphists say is before A.D. 148. This would put back the works of Dioscorides of Anazarba to the first century, supposing the coffer was to contain them, but this is in accord with modern views as to his era, because no one doubts now but that the three books of the περί φάρμακων σχευασίας composed by Nero's medical attendant Andromachos, the younger, make great use of Dioscorides' work. Also an author named Erotian who dedicated to Andromachos his "Lexicon to Hippocrates" cites Dioscorides. So also does Asklepiades, the younger, who refers to both Andromachos and Dioscorides. Some of these allusions may be to a medical author Dioscorides, "Phakas" or "Alexandrius," who served Ptolemy Auletes and Cleopatra, and it may be suggested that his works were those intended for custody in the coffer, but their length militates against the idea because his medical treatise occupied 24 books and his commentary upon Hippocrates seven.

Presupposing now that the coffer was probably made for a work of the best-known Dioscorides, Was the receptacle the correct size to contain the "De Materia Medica" in three rolls? This can be answered in the affirmative ecause the space would accommodate three papyri of from 40 to 50 feet each, which in very fine Greek writing would be ample for the five books. which in Sprengel's edition, including introduction and com-mentary, occupy two octavo volumes. The papyri of éditions de luce varied from 20 to 40 feet in length. The world has been almost provided with a papyrus of Dioscorides that would have perhaps decided these questions, for in the "Classical Quarterly" for

1908 a fragment of papyrus bearing his treatise has been published.
Finally, there remains the question as to whether the stone clat was intended merely to act as a storehouse for the papyri in the library, or whether it stood at the base of a statue of the author. For ourselves we are inclined to favour the second hypothesis, for not only have many statues of orators and authors been found holding bookrolls in their hands, but several are extant showing these volumes standing in boxes, or coffers called capse, upon the base or plinth upon which rest the feet of the statue. Three specimens of such may be seen in M. Reinach's "Répertoire de la Statuaire," vol. ii., and more may be found in Herr Birt's "Die Buchrolle in der Antiken Kunst."

THE GOOD SAMARITAN ABOVE THE SNOW-LINE.

THE unveiling of a monument has recently taken place to one who had 'scorned delights and lived laborious days" in the region of perpetual snow. St. Simeon Stylites, indeed, led a blameless life perched on the summit of a column. But Pietro Chanoux has a better title to canonisation, having lived not only "without sin," but in the service of man and in the cause of science, at a height compared with which the column of his ascetic counterpart was as the Tower of Siloam beside the snow-peak of Mount Carmel. It was in 1859 that the Hospice of the Little St. Bernard, as the last phase of a history that dates from Roman times, received from its patrons the Knights of St. Maurice, a new superintendent in the Abbé Chanoux. A proficient scholar in the theological sense, the young nominee was an ardent nature-student ssionately fond of mountain solitude in which the companionship of books and the flora and fauna of the region were indeed the "society" of his choice. Add to this a philanthropic spirit which found its special gratification in rescuing the strayed "alpinista" and in ministering to the wants of the poor families maintaining a struggle for existence under the sternest of conditions, and you have an ensemble of qualities that made the appointment to the custody of the Hospice nothing less than an "inspiration." For 50 years the good Abbé remained at his post, often anowed up for weeks on end, and only venturing abroad when his faithful scouts, the St. Bernard dogs, apprised him of the approach of some belated wayfarer whose strength had failed him under the bitter sky or in the assault of the tempest. But even indoors he was never idle, devoted as he was to Biblical study, or within the precincts of the Hospice to the tendance of the flowers which soon made his garden a "point of pilgrimage" for the botanist from every clime. Zoology, too, had a special charm for him, shown in the confidence he could inspire in the steinbock or the chamois which would, in stress of weather, come and take bread out of his hand, or in the birds which would fly to the Hospice from the pursuing storm or the predatory eagle. In midsummer, when for a brief space the access to him was comparatively easy, he was sought out by relays of visitors, from the Queen of Italy to the Italian or Swiss professor; from the nature-student, whether hailing from the British Isles or the British colonies, to the poet or the missionary eager to listen to his narrative of life and adventure above the snowline. His experiences as a pastor and as a rescuer of the imperilled wayfarer, taken down from his lips, will doubtis see the light some day; but the few publications of his own authorship with which he enriched his library of 4000 volumes are but the foretaste of what his writings, left in manuscript, will ere long reveal. For one thing, he was an accomplished meteorologist, so much so, that the Padre Denza of the Vatican Observatory, in acknowledgment of his contributions to the science, called the attention of the Order of St. Maurice to his observations, and an opportune enrichment of his "armamentarium meteorologicum" the result. He had just completed his half century of life at the Hospice when a brief illness carried him off on Feb. 9th last. Still active in mind, he had begun to fail in body-his evesight in particular having been injured by the constant glare of the snow—and amid the sorrowing demonstrations of the poor families to whom he had been a "refuge and a strength," he "entered into rest," felix opportunitate mortis. Proud of their compatriot and custodian, the Order of St. Maurice at once took steps to do honour to his memory, and commissioned the sculptor Signor Tancredi Pozzi with the design and work. This was completed within six months and a brilliant auditory, composed of the "light and leading" of Italy and Switzerland, listened to the orator of the occasion, Signor Paolo Boselli, secretary of the Maurician Order, on its solemn inauguration. The Abbé, his long robes fluttered by the mountain breeze and his white beard waving in sympathy, is represented, piccozza (spud) in one hand and an Alpine flower in the other-a felicitous work of art. On the pedestal runs the inscription :-

"Qui | perdieci lustri | l'Abate Pietro Chanoux | Rettore dell'Ospizio Mauriziano | adorò Dio | nella poesia dei cieli, delle nevi, dei fiori | Pensò ed operò | con anima ardente, gentile | per la Scienza e per la Carità | Lo spirito di Lui | veglia inseparabile | dal Piccolo San Bernardo."

[Here for 50 years the Abbé Pietro Chanoux, rector of the Maurician Hospice, worshipped God in the poetry of sky, of snow, and of flower; meditated and laboured with ardent amiable soul for Science and for Charity. His spirit keeps watch inseparable from the Little St.

Signor Boselli's discourse, a noble effort of Italian oratory, kept the audience for more than an hour in rapt attention as he dwelt on the "poetry of the mountain," on the chequered history of the Hospice, on the character, intellectual and moral, of its rector as a man, a priest, a nature-student, and a patriot, bringing vividly before the listeners (among whom were many of the poor mountaineers the

"grandi dolori" of the Abbé's sympathetic soul and the noble response they evoked from it in ceaseless thought and exertion for his fellow-man. Incidentally he reviewed his contributions to science, awakening the interest of the numerous nature-atudents present by indicating how much valuable observation and reasoning lies inscribed in the manuscripts one day to see the light. And so the touching ceremony (carried out with admirable success by the Order of St. Maurice) came to a close with the echo of the last automobile taking back the last relay of visitors, and with the return of its characteristic silence to the mountain left alone with its favourite son.

PTOMAINE POISONING.

To the Editor of THE LANCET.

SIR,—The frequency of death by ptomaines induces me to offer an instance of personal experience of ptomaine poisoning.

I am not aware if any of the numerous victims were enabled to describe their symptoms or of the treatment adopted in such cases; having attained my ninety-first year, it seems a remarkable escape. On Tuesday evening, the 24th inst., having swallowed some milk, I became aware of its impurity and immediately took three grains of permang. potass. and went to bed, continuing the dose at intervals during the night in aerated water. About 5 A.M. I was awakened by sharp twitching pains all over the abdomen, with retching I brought off only mucus. At 8 A.M. I took a teaspoonful of p. carb. liq. At 9 A.M. diarrhœa supervened, I felt dizzy, and fell. In half an hour I fell again and was helped to an easy chair from which I slipped off, being quite incapable (although conscious) owing to extreme debility. I was troubled with musca volitantes and lay on a couch dozing for an hour; took small doses of liq. strychning and dilute phosphoric acid. This relieved me, but the attack left me with my mouth extremely sore, so that I was unable to take any but spoon food for a week. I recovered gradually and am now convalescent.

I am, Sir, yours faithfully,
Deal, August 30th, 1909.

R. GOODWIN MUMBRAY.

DEODORISING BY ELECTRICALLY GENERATED OZONE.

THE Scientific American of Sept. 11th states that remarkable results have been obtained by an electrical ozone-generating apparatus recently installed at the public library on Michigan-avenue and Washington-street, Chicago. In spite of an excellent system of ventilation, complaints were made of the unpleasant odour from accumulated human emanations, and a new method was tried with a view to counteract it. Direct current at 110 volts was converted to alternating at 120 by a rotary converter, and the latter was stepped up to 8000 volts by a transformer. This high-tension secondary current was allowed to discharge between the plates of the ozoniser, through which the air led to the ventilating apparatus was drawn. Oxygen was thereby converted into ozone in sufficient quantity t neutralise any odour of animal origin.

THE PRODUCTION OF RADIUM.

To the Editor of THE LANCET.

SIR,—In your issue of Sept. 25th you say, "Reuter states that the Austrian Ministry of Public Works has received from the mines at Sankt Joachimsthal 10 grammes of radium which represent the entire production of 18 months." I venture to think you must have misread Reuter's telegram, which I think stated that 10 grammes of radium chloride, equivalent to 1 gramme of pure radium, had been produced. As this company is deeply interested in the production of radium from its own mine in Cornwall and being contractors to the Radium Institute I do not wish such a misapprehension to pass to the public as tha 10 grammes have been produced from Joachimsthal, under the cover your high authority. Pure radium means pure radium bromide, which radium chloride is equivalent to about 10 per cent.

I am, Sir, yours faithfully, F. H. NORTH.

The British Metalliferous Mines, Limited, Church-court, E.C., Sept. 27th, 1909.

THE ANTIQUITY OF NOISE.

A FREQUENT correspondent writes: "Noise and the habit of being noisy are manifestly very ancient. Indeed, just as the chop and steak are probably primeval forms of food, known to the worshippers of Odin and Thor, so loudness of voice and heaviness of foot were doubtless leading attributes of our early Saxon ancestors. Chops, steaks, and noise are peculiar to country inns, from the hedge-side ale-house to the family and commercial hotel of some pretensions in county towns, for these fine old institutions are of great antiquity and have been centres of social life, and in some sort of civilisation, almost as long as parish churches. It is the custom to praise the inn, and an old poet is cited who always found his kindliest welcome there, but the very fact that writers approve the hostelries of England shows them to be men of iron nerves, or more probably persons who never sleep away from their quiet suburban homes.

The writer of these brief remarks, as a devotee of Dickens and also of pedestrianism and the cycle, is constantly benighted in country inns, and it is with the greatest unwillingness that he testifies against their noisy side, for he loves their immemorial associations. Still at times one must be just and outspoken. The diary of a recent night of almost complete insomnia at Winchester should be of some little interest to persons interested in social history in the year 1909

10.50 p.m.—To bed after a long cycle ride in the teeth of an obstinate north-easter.

11 p.m.—Settle down to sleep after reading a dull political novel.

12 p.m.—An infinitude of bells, clocks, and domestic carillons, enough to awake the Seven Sleepers, pervades the air for 15 minutes. The performance is charming, but unsuited to the midnight hour. Old Tom Paine, the bad, bold unbeliever of the French Revolutionary epoch, cursed bells in a curious pamphlet, and really in this matter he deserved well of nervous people with brains, who and the attainment of sleep no easy matter at any time.

12.30 p.m.—Enormously loud walk-round through all the passages of the honourable old hotel by 'Boots,' a young man whose feet are large and whose boot-soles are certainly more than an inch thick.

18.40.—The writer relights his candle and continues reading dull

12.60.—Ebullient good-byes at a back-door. 'Good-night' is yelled by a voice, 'See yer termorrer: Don't forgit,' &c., &c.

1.—A motor roars itself into action and there is general conversation by shrill voices.

1.30.—A fiend with boot-soles at least three inches thick proceeds slowly all over the hotel, slamming doors with vigour. The putting out of his boots is a cataclysm in the way of sound. If we had good light, a cup of tea, some biscuits, papers, pens, and a writing-desk, we would resume our versified translation of Propertius.

1.30.—Seven, yes, seven motors roar by, screaming like banshees

or playing half tunes.

2.—The "workers" come forth. They march by in boots of thickness indescribable. They may be hop-pickers. Immediately under the writer's window they roar greetings. "Ullo, Arree," a beast that must be quite familiar to all of them, is repeated again and again.

5.—Clocks, bells, and two howling dogs. We resume our novel and

begin to think of all the unpleasant things that in daylight we are able to disregard. Query: Does one 'look before and after' as clearly as one might in daylight?

3.15.—Creaking in all the passages.

4.- Early sparrow begins to thunder, for sparrows do thunder in the early morning.

4.30.—Passage of a motor-drawn caravan.

5.—General walk-out of gardeners, milkmen, and others, with loud bangs and clinks.

6.—Loud choruses from industrious people, who do not sympathise with stay-a-beds. Afterwards a short period of insensibility, broken by pungent nightmares.

8 o'clock.—Thundering knock at door. 'Will you 'ave fish for breakfast? We only 'ave kippers!' (We are only twenty miles from the sea and a fishing fleet. God have mercy upon us!)

But the above is no exaggeration. It is a twentieth experience at least. As a recent writer in a lay paper has pointed out, there is reason to believe that inns are living on their reputation, and that their standard of comfort is ancient. It is almost archaic; it is coeval with the days of the Vikings.

Whether noise is wholly evil in itself is another question. Gould of Philadelphia has suggested in a work upon the 'History of the House,' vermin must have had a selective influence in the Middle Ages, for the bites of fleas and pediculi must have tended to weed out the nervous and the delicate, who were driven thereby to madness and sometimes self-destruction. And thus the race was strengthened. A fortiori noise must have played an immense rôle in the Dark Ages in ridding society of weaklings, who fell victims to insomnia just as others did to the irritation of

"COLDS" AND CLOTHING.

"D.Sc., M.D.," writes that he is aged about 40 years and has always been very sensitive to changes of temperature. Living in the south of England he spends a considerable amount of time in the open air, particularly sailing, and finds in winter always, and often in summer when the day turns cold or wet, that on his return home he feels very cold, chilled throughout, has some huskiness of the voice or dry condition of the throat, and is very tired and languid. His temperature is then usually subnormal. After sitting over the fire and getting thoroughly warm he feels more comfortable, but nearly always has a restless night and feels cold all the next day. This sensation may pass off without any unpleasant sequel, but is sometimes followed by a temperature of 1078 Exerct threat, headaghe achieve in light and general. perature of 103° F., sore-throat, headache, aching in limbs, and general prostration lasting three or four days, very like an attack of so-called influenza. A night call is nearly always followed by the same languor, chilly feeling, and general malaise the next day. Walking, cycling, or other exercise in the open air when the weather is cold or damp is followed by similar symptoms, and he has taken to sailing in order to get fresh air without exertion. He would like to have suggestions as regards cause, prevention, treatment, and clothing. As there has been a tendency recently to decry woollen and to praise linen and cotton underwear he would be glad to have opinions on this subject.

Pharmacy.-We are in accord with much which our correspondent writes, and, indeed, more than one of his sentiments have been at different times freely expressed in our columns. It is the educational course of the student which is largely to blame. Very few students are taught the art of prescribing in any systematic manner. consequently experience very real convenience from the use of such ooks.

Medical Diary for the ensuing **Week.**

ROYAL SOCIETY OF MEDICINE, 20, Hansver-square, W.

THERAPEUTICAL AND PHARMACOLOGICAL SECTION (Hon. Secretaries—J. Gray Duncanson, H. Charles Cameron): at 4.30 p.m.

On the Teaching of Therapeutics in the Hospital Wards.
The Discussion will be opened by Sir Clifford Allbutt.
Prof. W. Osler, Dr. Harrington Sainsbury, Dr. J. Calvert,
Dr. Robert Hutchison, and Prof. W. B. Dixon will take part in

Any Fellows or Members desiring to speak will kindly send their names to Dr. Gray Duncanson, Wingfield House, Shooter's Hill, S.E.

CLINICAL SECTION (Hon. Secretaries: H. D. Rolleston, M.D., Albert Carless, M.S.): at 8 P.M.

Dr. Rolleston: Pigmentation of the Mouth in a Case of Grave

Anemia.
Mr. Albert Carless: Excision of both Superior Maxilles.
Mr. James Sherren: Meckel's Diverticulum with Contained
Calculus.

Dr. Finsi and Dr. Ernest Shaw: Carcinoma Mamme treated by Radium (further report).

At the Royal Bye Hospital (2 P.M.), the Royal London Ophthalmic (10 A.M.), the Royal Westminster Ophthalmic (1.30 P.M.), and the Central London Ophthalmic Hospitals operations are performed daily.

EDITORIAL NOTICES.

IT is most important that communications relating to the Editorial business of THE LANCET should be addressed swelusively "To THE EDITOR," and not in any case to any gentleman who may be supposed to be connected with the Editorial staff. It is urgently necessary that attention should be given to this notice.

It is especially requested that early intelligence of local events having a medical interest, or which it is desirable to bring under the notice of the profession, may be sent direct to this office.

Lectures, original articles, and reports should be written on one side of the paper only, AND WHEN ACCOMPANIED BY BLOCKS IT IS REQUESTED THAT THE NAME OF THE AUTHOR, AND IF POSSIBLE OF THE ARTICLE, SHOULD BE WRITTEN ON THE BLOCKS TO FACILITATE IDENTI-FIGATION.

Letters, whether intended for insertion or for private informa tion, must be authenticated by the names and addresses of their writers—not necessarily for publication.

We cannot prescribe or recommend practitioners.

Local papers containing reports or nows paragraphs should be marked and addressed "To the Sub-Editor."

Letters relating to the publication, sale and advertising departments of THE LANCET should be addressed "To the Manager."

We cannot undertake to return MSS. not used.

MANAGER'S NOTICES. TO SUBSCRIBERS.

WILL Subscribers please note that only those subscriptions which are sent direct to the Proprietors of THE LANCET at their Offices, 423, Strand, London, W.C., are dealt with by them? Subscriptions paid to London or to local newsagents (with none of whom have the Proprietors any connexion whatever) do not reach THE LANCET Offices, and consequently inquiries concerning missing copies, &c., should be sent to the Agent to whom the subscription is paid, and not to THE LANCET Offices.

Subscribers, by sending their subscriptions direct to THE LANCET Offices, will insure regularity in the despatch of their Journals and an earlier delivery than the majority of Agents are able to effect.

THE COLONIAL AND FOREIGN EDITION (printed on thin paper) is published in time to catch the weekly Friday mails

to all parts of the world.

The rates of subscriptions, post free, either from THE LANCET Offices or from Agents, are :-

FOR THE UNITED KINGDOM.

One Year £1 12 6
Six Months £0 16 3
Three Months 0 18 2
Three Months 0 18 2
Three Months 0 8 2

Subscriptions (which may commence at any time) are payable in advance. Cheques and Post Office Orders (crossed "London County and Westminster Bank, Westminster Branch") should be made payable to the Manager, Mr. CHARLES GOOD, THE LANCET Offices, 423, Strand, London, W.C.

TO COLONIAL AND FOREIGN SUBSCRIBERS.

SUBSCRIBERS ABROAD ARE PARTICULARLY REQUESTED TO NOTE THE RATES OF SUBSCRIPTIONS GIVEN ABOVE. It has come to the knowledge of the Manager that in some cases higher rates are being charged, on the plea that the heavy weight of THE LANCET necessitates additional postage above the ordinary rate allowed for in the terms of subscriptions. Any demand for increased rates, on this or on any other ground, should be resisted. The Proprietors of THE LANCET have for many years paid, and continue to pay, the whole of the heavy cost of postage on overweight foreign issues; and Agents are authorised to collect, and generally do so collect, from the Proprietors the cost of such extra postage.

The Manager will be pleased to forward copies direct from the Offices to places abroad at the above rates, whatever be the weight of any of the copies so supplied. Address— The Manager, The Lancet Offices, 423, Strand,

LONDON, ENGLAND.

SOLE AGENTS FOR AMERICA-Messrs. WILLIAM WOOD AND Co., 51, Fifth Avenue, New York, U.S.A.

An original and novel feature of "THE LANCET General Advertiser" is a Special Index to Advertisements on pages 2 and 4, which not only affords a ready means of finding any notice but is in itself an additional advertisement.

Advertisements (to insure insertion the same week) should be delivered at the Office not later than Wednesday, accompanied by a remittance. Answers are now received at this Office, by special arrangement, to advertisements appearing in THE LANCET. The Manager cannot hold himself responsible for the return of testimonials, &c., sent to the Office in reply to advertisements; copies only should be forwarded.

Cheques and Post Office Orders (crossed "London County and Westminster Bank, Westminster Branch") should be made payable to the Manager.

Mr. Charles Good, The Lancer Office, 423, Strand, London, to whom all letters relating to Advertisements or Subscriptions should be addressed.

THE Lancer can be obtained at all Messrs. W. H. Smith and Son's and other Railway Bookstalls throughout the United Kingdom. Advertisements are also received by them and all other Advertising Agents.

An Address

SOME THOUGHTS ON CAUSATION IN HEALTH AND DISEASE.

Delivered at the Opening Coremony of the Family of Medicine in the University of Leeds on Oct. 1st, 1909,

By THE RIGHT HON. LORD JUSTICE FLETCHER MOULTON, P.C., F.R.S.

LADIES AND GENTLEMEN,—I am fully sensible of the honour which your faculty has done to me in asking me to give the address to you at the commencement of your university session. But the honour has its difficulties. I know well the value of special study in any branch of science and how presumptuous it is for those who have not trodden that toilsome path to venture to speak before those who have. But this must have been equally well known to those who chose me for the task, and they must have believed that nevertheless a layman like myself might find some subject bearing on your studies upon which he might with propriety ask your attention for a short time, and I am bound to accept their view.

There is one characteristic of curative science which justifies the expectation that all who are capable of understanding scientific reasoning will have given some attention to it. It is that we are interested in its results as deeply as you are. It is true that we are not qualified to rank ourselves among the combatants, but the prize that is being fought for is our own health and our own lives as much as yours, and it is no wonder, therefore, that the movements on the field are scanned with the closest attention by us though we are only spectators. And it is less difficult for me to find some common ground on which I can speak to you because the period of my thinking life has been nearly co-extensive with the remarkable enlargement of our field of knowledge which followed the discoveries of Pasteur-discoveries which revolutionised our conceptions as to the causation of disease. The aid of experiment has been called in to an unprecedented extent to solve riddles which formerly would have been thought to belong solely to the domain of clinical observation and its attendant empiricism. The work that experimental science has thus done is of such a nature that it can to some extent be appreciated even by those whose training in science has been of a general rather than of a special character.

I can claim for myself to have been a close observer of these advances in science from the time when at college I first read the lectures of Lord Lister on the then novel application of antiseptics to surgery. In following these discoveries I have striven to realise to myself the world of minute life which they reveal, the working of the laws which govern it and its influence on health and disease, and I have thought that I can best occupy your time if I put before you the picture which has thus been formed in my own mind of the interaction between ourselves and this other world by which we now know ourselves to be surrounded. By so doing I am freed from the danger of appearing to try to teach those who know so much more than I or to ape an authority which I do not possess. I shall only aim at showing you how these great discoveries, which will always make our age famous, shape themselves to the mind of a humble looker-on, and if I had to put a descriptive heading to this address I should plagiarise from Robert Browning and entitle it, "How it strikes a Contemporary."

In reviewing the forty or fifty years that have elapsed

In reviewing the forty or fifty years that have elapsed since the birth of the new conception of the nature and causation of infective disease I mentally divide it into two epochs, in the first of which scientific thought concerned itself mainly with the attack of these our unseen enemies, and in the second with the defence. This division is necessarily a rough one and much overlapping must be admitted. The new knowledge early showed that it brought with it new power, and some of its most brilliant practical applications belong to the first period. On the other hand, our knowledge of the organisms that attack us is still being added to, and much yet remains to be done in this field. Nevertheless, the No. 4493.

division into the two periods is not unscientific, and it is useful in clearing our ideas. The ascertainment and the comprehension of nature's defence against micro-organisms came long subsequently to the discovery that to their action were due the numerous infective diseases to which men and animals are subject.

I do not propose to dwell at any length on the events of the first period, which must be well known to you all. It began when the classical experiments upon anthrax demonstrated that this fatal disease was due solely to the presence of a definite micro-organism. A like demonstration rapidly followed in the case of chicken cholera. But these and other subsequent demonstrations had consequences extending far beyond the instances to which they particularly related. The scientific world recognised that for the first time infective diseases had been traced to their true causes. Up to that time the causation of such diseases had been the subject of conjecture and hypothesis only. Doctors and chemists had talked learnedly of such and such a disease being due to a particular virus, the existence of which was assumed, not proved. But now one infective disease after another had been tracked experimentally to its cause, and in each case that cause had been found to be the invasion of a specific micro-organism. In the presence of such demonstrations conjectural hypotheses could no longer stand. The onus probandi was rightly held to be changed, and in the absence of proof to the contrary infective diseases were taken to be due to the presence of such organisms. All reflection as to the characteristic phenomena of infectious diseases confirmed this view. The circumstances under which infection ordinarily takes place are such that they preclude the idea of anything but a microscopically small quantity of matter being transferred—an amount so small that any physical or chemical effect of the transferred matter must be negligible -and yet in the resulting disease not only are the disturbances of the whole organism most formidable but the actual amount of infective matter generated must to all appearance be illimitably greater than that which originally caused it. All this is so strikingly in harmony with the almost infinite powers of self-multiplication of microorganisms that when the mind has become familiarised with the idea that micro-organisms and infectious diseases may stand in the relation of cause and effect, it becomes difficult to imagine that the cause of such diseases can be of any other nature. One instinctively thinks of living germs as the cause of all infective disease. And this instinct has not proved misleading. Gradually the list of infectious diseases. that can actually be traced to specific micro-organisms has swelled and in it are now found many of the most serious that afflict mankind, and no one doubts that it is only due to our imperfect methods of investigation that the list does not include all.

A curious extension of our knowledge has resulted. Although, no doubt, the original impulse to the study of the causation of disease by micro-organisms was given by the case of infectious diseases, it has turned out that such diseases by no means furnish the sole or even the most remarkable instances of such causation. No one would have called scrofula an infectious disease, and few would even have applied the term to its companion phthisis, yet they are now known to be due to micro-organisms, and probably the same may be said of other diseases of the respiratory system. realise now that although infectiousness implies that the disease is due to living germs the converse is by no means necessarily the case. In truth, infectiousness is an accidental consequence, due to the infected organism giving off contaminated matter in some form in which it is likely to be transferred to other organisms. In many cases, such as small-pox and influenza, we are wholly ignorant of the way in which this transference is effected, but no one doubts that it occurs. But if the infected organism has no tendency to give off infected matter, or only gives it off in some form not leading to such transference (as, for instance, in furunculosis or localised tuberculosis), there is no reason why the disease should be infectious. Hence it is impossible as yet to tell how widely the microbic origin of disease extends. It may well be that some constitutional diseases as yet unsuspected may ultimately prove to be due to micro-organisms that have established themselves in the system and give evidence of their existence only by the mischief which they work. Nor does this exhaust the evil wrought by our minute foes.

Many kinds of micro-organisms become permanent residents with us—kept under in normal health but ready to multiply and become dangerous as the sequelæ of disturbances such as those produced by a serious illness of almost any type. In short, such organisms may claim to be wholly or partially the cause of most morbid conditions of the system, and it is no exaggeration to say that the discovery of means of successfully combating them merits to be regarded as the greatest problem of curative science and one of unrivalled importance to the world at large. I shall now consider what the new knowledge has taught us as to our defence against these ever-active enemies.

To understand and appreciate this aright one must first get a clear idea of what is to be defended and how it is situate. The human organism, like to that of all the higher animals, must be regarded as being composed of cells of varied structure, arranged no doubt in groupings essential to their functional activity, but nevertheless possessing each its individual life with all its necessities. Each cell must receive due nourishment and must be protected from influences injurious to its individual vitality if it is to continue its effective life. This is, of course, true of all living cells, however independent their existence may be. But a cell in a complicated organism differs in two main characteristics from those that live a wholly independent life and who represent doubtless its remote ancestors. In the first place by changes both in structure and function it has lost the power of "fending for itself." It has not only lost the power of locomotion, but it has lost in most cases entirely, in all cases to a great degree, the powers of seeking and capturing its prey which exist even in the most primitive forms of life. On the other hand, it has acquired in a high degree certain capacities of a kind that would be useless to the independent cell in its struggle for existence, but which are essential to the captive cell if it is to perform its special function in the organism of which it is a constituent. In a word, the cell has become highly specialised at the cost of word, the cent has become nightly specialised at the cost of its general capabilities. It presents an example of the last stage of the process which Haeckel termed "the Division of Labour in Nature." Like to the members of a civilised com-munity each cell does some special work and becomes adapted to do that work and only that work well.

But if Nature in building up sentient beings endowed with their wonderful capacities is to have the advantage of these highly specialised cells, she must be content to take the responsibilities they bring with them. Those that she uses for her purposes are, indeed, far removed from the simple ancestral forms that seem to find means of existence everywhere. It is not to be wondered at if for the mechanism of the sense-organs, and still more of the brain, of a vertebrate, cells must be so highly specialised that all their vitality seems concentrated in the power to respond to some one particular stimulus or to manifest some one particular reaction. But in proportion to this concentration on their special work comes the need that all their wants should be catered for by the organisms as a whole. This implies not only the provision of the precise nourishment which they require, but the protection from all that would be hurtful. With the high specialisation has come increased delicacy. You have made your flowers more splendid by making them hot-house plants. You must now shelter them from every breath of the cold wind outside.

To maintain unchanged the environment of these delicate cells is Nature's task and she performs it wondrously. The body as we see it is like to a fortified city: it shows only the outer ramparts which nature uses to protect the community within from disturbance coming from withoutthe first line of her defensive works. If we look within we find further provision for excluding interference with the life of the individual cell. Each cell is in a world of its own cut off from the external world. Penned up amongst its fellows its real environment is represented by the bloodstream which circulates all around. This is to it the external world in which it lives and works and from which must be satisfied all its needs. The blood brings to it its food and the oxygen necessary for its work, and removes directly the main combustion products and indirectly all the products which result from its activity. The blood is therefore the environment which Nature must keep constant that the existence of these highly specialised cells may be preserved. Consequently we find in the body manifold adjustments to maintain the blood uniform in quantity,

temperature, pressure, gaseous contents and fluidity, and though its composition is such that it defies rigorous analysis we can see enough to know that within certain limits it alsois uniform. Indeed, so limited are the specialised powers of the cell that it is more than probable that it would be incapable of feeding itself from any other medium than one just so composed.

But these delicate cells are not all specialised in the same way. They differ widely in structure and function, and thisvariety of specialisation necessitates a corresponding variety of provision for their individual needs. Daily the complexity of composition of the blood stream is becoming more manifest. Everyone remembers the astonishment and delight with which the discovery of the cure for myxcedema was hailed. What did it tell us? It showed that for some groups of cells necessary for the proper working of the organism as a whole a special food of definite chemical composition must be provided; that if this food was not presentthe body became diseased; that in the healthy body thisfood was elaborated in the thyroid gland, but that if that gland was incapable of performing its work the food might be brought from without and the cells that needed it would be equally satisfied with the provision so made. How many other such special foods for special types of cells there may be in the blood we cannot guess, but already the morbid developments which follow on injury to apparently useless organs warn us against viewing the thyroid gland as an exceptional case. And after all such marked and discrete essentials are only simple features of the blood stream. The modern discoveries to which I shall presently refer testify to. and give us glimpses of, an almost infinite complexity far beyond the mere presence of such well-defined components.

It is in this the true environment of the cells of which the body is composed that we must study both the attack and the defence in the war with micro-organisms if we would understand them aright. For not only is the blood the very life of the organism by reason of the all-important services that it must perform, but it supplies the means of complete intercommunication. Once get access to the blood stream and the way is open to every cell. To recur to the metaphor of the fortified city, the blood channels are the streets which lead to each house. And the metaphor is still more apt in this case because, as in the case of a city, these channels must be kept free and open by reason of the necessities of the citizens themselves—that is to say, of the cells. Their own nourishment and life depend on the existence of a free circulation, and, whether there be enemies within the streets or not, they cannot close them except at the cost of the death of the secluded part. In this the blood circulation differs from the secondary and more sluggish lymph circulation where nature seems able to set up barricades in the form of glands to arrest and partially cut off intercommunication. The blood stream must be kept free both to friends and to such foes as have passed the outer defences and gained access to it. And it would seem that a micro-organism that has won its way to the blood stream must find surroundings almost ideally fitted for its growth. Experience has taught us how numerous are the types of microbes that actually thrive on the blood fluids, and the well-known adaptiveness of micro-organisms in general makes us feel that but for some hidden cause the rich nourishment that is on its way to feed the specialised cells of the body would be an admirable nidus for them and suffice for almost infinite multiplication. What can be found to check such invasions?
Those who study Nature as did our great poet,

"considering everywhere Her secret meaning in her deeds,"

and who would measure the probable consequences of such an invasion by the precautions that nature takes to prevent it, must find abundant evidence that she regards it as a grave danger. The skin, her first line of defence, is soelaborately constructed and so efficient that though microbes swarm around and even upon us they rarely effect an entrance while the skin is healthy. How successful is this defence is shown by the difference it used to make in surgery whether in an accident the skin was broken or not, and the gratitude that we rightly feel for the triumphs of the antiseptic and aseptic methods is a confession of the importance of the defence of the skin for which these methods provide valuable though imperfect substitutes. If by a wound this defence is broken down the blood pours out to form a clot and thus, if possible, to protect the exposed surfaces. Should microbes

succeed in passing through the skin Nature is active in her efforts to minimise the evil and restrict its area. She seeks by inflammatory processes to prevent communication with the general circulation—building a rough but efficient wall which she can defend more or less well and through which she can and does pour her defending forces. In all this she acts as does the commander of a beleaguered fortress when a practicable breach is made in his walls. He builds a rough barricade behind the breach so as to keep the foe from penetrating into the town even at the cost of abandoning for a time a part of his territory and leaving it more or less completely in the enemies' hands. Thus we see colonies of microbes which are capable of producing a general infection, such as anthrax or streptococcus, successfully localised and kept outside the general circulation by such means.

But there are, and must be, weak spots in these defences. Like every beleaguered fortress, the body must be provisioned from time to time, and in this case it must also be constantly provided with oxygen. It is the portals at which air and food are taken in which are so difficult to defend, and it is through them that lodgments are generally made. But whether they be effected thus or otherwise, it is inevitable that from time to time invasions must take place which achieve either partial or complete access to the blood stream, and in dealing with disease it is these that we have to consider. In other words, the body must be looked upon as a fortress whose external defences against micro-organisms cannot be trusted and are not in themselves sufficient to protect the environment of the cells of the body.

Let me now turn for a moment to an apparently different class of case. You see a ship that has come safely through a stormy voyage. You know that the waves must have buffeted her, that she must have been rolled from side to side and yet she has emerged safely. You say that this is due to her stability. Yet she is not stable if stability means that she can defy the forces that bear on her to move her from her normal upright position, for you know that the alightest roll of the sea or even the slightest puff of wind will make her heel over. She is stable because when made to lean over there is thereby generated a system of forces tending to return her to her place—called, I believe, by naval architects the "righting couple"—which grows greater the greater is the displacement and thus ultimately becomes sufficient to overpower the disturbing forces. Unless this be present the ship must inevitably capsize when made to lean over, and as you are sure that in the storms with which she has met she must again and again have been rolled about by wind or waves, and as you see that she has arrived safely you know that her construction must be such that disturbances tend to right themselves. A like conclusion forces itself upon us when we think of a living organism which throughout its whole life has been exposed to attacks from the micro-organisms that surround it, some of which attacks must inevitably have led to successful lodgments of the enemy within the organism. Could it have survived-Nay, in this case, remembering that the organism is itself the offspring of a long line of development through individuals who have lived their lives and continued their race, we may ask the question of ourselves in the still more striking form-Could the organism ever have existed had not these attacks in some way or other operated to bring into existence the necessary forces of defence?

To bring the metaphor home, let me take a severe but not fatal case of an infectious disease, such, for instance, as The original infection is minute, and the typhoid fever. body into which it is conveyed is healthy, yet the microbe increases beyond all power of calculation and assailing the vital functions of the body brings the patient to the verge of the grave. At that moment when his strength is at its lowest, when his vital powers are well-nigh exhausted, when probably each microbe of the original infective matter is represented by countless millions of equally virulent microbes as capable of infecting a healthy man as were the original invaders—at the moment, in short, when the invaders' strength is so high and that of the organism is so low the tide of battle turns and the enfeebled body repels an enemy immeasurably more strong than that which the healthy body failed to keep in check. Some righting force, some powerful influence tending to bring back the organism to its normal state must have been developed during and by the sickness which makes the sick man triumph where the healthy man could not resist. Like to the ship in the storm the "righting couple" which draws it back, springs from the danger itself and proves itself to be strongest when the storm apparently is doing its worst.

While the phenomenon of recovery from a disease caused by an invasion of microbes capable of limitless multiplication points with certainty to the generation of some such righting force there is another phenomenon equally familiar to us which ought to have taught us an equally valuable lesson. Take the case of a man who has just recovered from an infectious disease. He may be in the company of convalescents like himself who would probably be dangerous centres of infection to a man who had not had the disease. But no one expects him to take it. Experience has taught us that for a time there is no fresh susceptibility. The extent of this so-called immunity varies within the widest limits from a long and often life-long protection in the case of small-pox to a short and uncertain one in influenza. sometimes fails, as in the case of relapses, but on the whole it is the ordinary accompaniment of recovery from such diseases. It shows that the effects of the righting force last after it has done its primary work of restoring the organism to its normal condition.

It was in the direction of this immunity that the first practical application of the new knowledge was made. Pasteur, anxious to protect sheep from the deadly anthrax, and having found out a method of producing an attenuated strain of the microbe, hit on the idea of inoculating sheep with this weaker form of anthrax microbe. It gave the sheep a mild attack from which they recovered naturally. This left a state which, though they could not wholly resist a virulent inoculation, enabled them to bear such an inoculation without serious disturbance, and thereafter they were found to be immune for a considerable time. They might be put among an infected flock or even inoculated with virulent anthrax

without taking the disease.

Although the novelty and wide practical outlook of this discovery excited universal interest, it led to little speculation as to the modus operandi of the process. regarded, I think, both by Pasteur and the world at large, as being merely a case of putting the animal in the position of having had the disease, and the brilliancy of the discovery was considered to consist in that it taught us to do this without endangering the life of the animal. Few asked them-selves how it was that an animal was less likely to get the disease because it had recently had it. This was so wellknown a phenomenon that it was accepted as natural without further inquiry. The explanations that passed current among those that happened to think about it were either that the microbes exhausted the nourishment to be derived from the blood or that they fouled their habitat by their own products. In either case it would follow that the blood would be left in a condition in which it could not support that form of life, and the period of immunity was supposed to measure the time which the blood required to return to its normal state. Neither of these conjectures was supported by experiment, and both had soon to disappear in the presence of further knowledge.

The insufficiency of such explanations is made manifest when we consider the remarkable discoveries relating to diphtheria, which, to my mind, inaugurate the next stage in the advance of our knowledge. It was found that inoculation of the serum of the blood of an animal that had recovered from diphtheria would enable an animal to support an inoculation of diphtheria itself that would otherwise have proved fatal. If we had to choose between the two hypotheses that I have mentioned such a result must make us reject the suggestion that immunity is due to the exhaustion of the nutriment in the blood, but it might be held to support the rival theory. But it was established that the diphtheria microbe works not by spreading throughout the organism but by producing from comparatively localised colonies an intensely powerful poison (or toxin, as this class of poisons is now termed), and the disease we know as diphtheria is the result of this chemical substance, and can be produced by injections of it without the intermediation or presence in the body of any microbes. It was also shown that the protective serum of which I have spoken is produced when this poison is injected into animals in non-fatal doses and is now universally obtained in this way. It is not necessary that they should have been infected with diphtheria microbes. The injection of the poison is equally followed by the production of the protective serum.

I need not tell you of the practical importance of this discovery. But its theoretical importance is equally remarkable. The serum so produced protects animals against the consequences of injections of the toxin which originally caused it to be produced. In other words, it contains some substance which is an antidote to that toxin. So absolutely is this the case that it is found that when the toxin and the serum are mixed in proper proportions the mixture is a harmless neutral fluid that can be injected without producing any toxic effects. And remember that this antidote was generated upon the injection of the poison. It did not exist previously in the blood. It was Nature's response to the attack. The attack consisted in introducing into the animal from which the serum was obtained a dose of a certain poison—a poison no doubt of a complex proteid type, but none the less a definite chemical poison—and to this the organism responded by generating its antidote. We have here no intermediate and undetermined action of living microbes. No doubt in past ages such an attack must have been made by diphtheria microbes which would have generated their poison and set it free to work its mischief. But in the production of serum the action of the microbes is eliminated altogether, and it is found that the mere presence of the poison leads to the generation of an antidote which, if generated quickly enough and copiously enough, nullifies the poison entirely. The immunity that he enjoys shows that this is the case in the horse. In man the large mortality in diphtheritic cases shows that if the attack is a bad one the response may not be adequate in amount, or-which is more probable-that it comes so slowly that the poison has had time to do fatal damage before the antidote arrives. By the serum treatment supplies of the antidote are brought from without which protect the system until the attack is over or until the organism is in a position adequately to defend itself.

I shall never forget the impression made upon me when years ago I first realised the meaning of this mode of generation of diphtheritic antitoxin. It seemed to open up a new world of vital activities to find that on the injection of a poison a chemical substance capable of neutralising the injected poison and that alone should thus be naturally produced. For that which is generated is not of the nature of general protection. It is specific. It is an antidote to that particular toxin and to no other. I was used to such vague phrases as "rousing the resisting powers of the system" and the like, and it would not, I think, have astonished me had it been shown that such poisons stimulated elimination or some other defensive action of the organism. But I was not prepared to find that Nature, like a skilled boxer, hit straight back at its assailant and at him alone. This lesson has often been repeated since. I do not allude merely to the case of tetanus, in which are repeated the phenomena which I have described in relation to diphtheria, but to the investigations which show that when a foreign proteid substance is introduced into the blood an antibody is normally formed therein which has a special effect on it and it alone, usually in the direction of neutralising it. Thus by repeated small injections of snake poison you can get a serum that has the properties of an antidote to that particular venom. The instances of this strange phenomenon are so varied that they point to the existence of a general law in the case at all events of the higher animals, although, of course, we do not as yet know the conditions and limitations of its action so as to be able to formulate it with exactness. That it has become a general law seems to be supported by our finding that it is followed in cases in which we can see no possibility of its having ever been serviceable in the struggle for existence. Thus the blood of one kind of animal has generally no dissolving powers on the red blood corpuscles of another kind. But if the former animal be subjected to inoculations of blood from the latter its blood gradually acquires a power of dissolving those corpuscles. Its behaviour will not be changed towards red blood corpuscles in general, but only towards those coming from the kind of animal from which the inoculations were taken or some animal closely related to it.

Let me pause here a moment to consider how far we have got in our subject. We have found that in the cases of which I have spoken there is a true righting force. The poison that is introduced starts the manufacture of its antidote. The organ is protected by that which springs into existence on the attack. And the most characteristic feature of these

phenomena is that the remedy is specific—it avails against the poison which creates the need for it and against no other.

It would seem as though we had wandered somewhat from the subject of micro-organisms in dwelling thus upon the action of the organism towards proteid poisons. But the digression is in appearance only. Not only are microbes the chief means by which such poisons are introduced into the system, but, conversely, there are few microbes which when they have gained an entrance into the system do not generate toxins to the direct action of which much, if not all, of the mischief must be ascribed. In some cases, as, for instance, in diphtheria, the microbes do not seem to be too numerous or too widely distributed in the body to be dealt with by natural processes to which I shall presently refer and the danger wholly consists in the quantity and virulence of the poison which they generate before they can be overmastered. I liken such microbes in my own mind to invaders who promptly start conflagrations. They may be a mere handful in number, incapable of effective resistance to the forces that will be brought against them, but the conflagrations they have started must be put out or there will be no city to save. This is the sole service which the antitoxin renders. I can see no ground for thinking that it affects the microbes themselves; indeed, they can readily be cultivated in it. If they are got rid of it must be by other agencies. It is to these agencies that I wish now to direct your attention—the agencies that get rid of the invaders themselves. In other words, What is the nature of the righting force which gives the necessary stability to the organism in the face of an invasion of living microbes and restores it to its normal condition?

I have already referred to the experiments of Pasteur by which he gave to sheep protection from anthrax by inoculating them with cultures of living anthrax of graduated Our knowledge of the nature and origin of this "righting force" starts with the discovery that in certain cases—such, for example, as typhoid fever—an analogous protection can be obtained by inoculations of dead cultures of the corresponding bacilli. The change seems at first sight to be but small, yet in reality it is of vast importance both practically and theoretically. In practice it makes it possible to give substantial immunity to the individual without requiring him to undergo an actual attack of typhoid fever with all its attendant risks to himself and others. But it also teaches us much as to the nature and causes of immunity in that it shows that the introduction of dead microbes into the body is sufficient of itself to bring about changes which for a longer or shorter time prevent the living microbe from making good its footing there. This cannot be due to any exhaustion of nutritive material, because the inoculated microbes are dead, nor to pollution by microbic products to such an extent as to render the body incapable of supporting that form of microbic life, because the total amount of the inoculations represents but a small fraction of the quantity of microbes that must be present in an actual attack of the disease. No such simple application of the laws that limit the multiplication of microbic life suffices to explain the phenomenon. It forces us to realise that we are here in the presence of some reaction of the organism which results in rendering it in the future an unsuitable habitat for that particular microbe.

We turn to the blood-stream as the natural, and perhaps only possible, seat of such a defensive action. The determination of the changes effected in it is facilitated by the fact that with proper precautions a sample of the fluid portion of the blood can be drawn off and kept for a time without substantially affecting its properties. To this can be added living microbes in any desired numbers, and thus the effect of the blood of an immunised animal can be directly observed and compared with that of a nonimmunised animal. It is thus found that the blood may become hostile to the microbe in more than one way. In the first place it may become directly poisonous to it. This property may be present to some extent in normal blood as in the case of the typhoid bacillus, but even in that case it is largely increased in the immunised person. It is obviously due to the production in the blood of some substances which combine with the body of the bacterium because the destructive action can be removed by adding to the fluid a sufficient quantity of bacteris-living or deadwhen it becomes capable of supporting living bacteria in the

ordinary way. Let me call your attention to the lesson this teaches us. The direct effect of the introduction of bacteria into blood is therefore to lessen any bactericidal power it possesses by using up pro tanto the bactericidal substance. On the other hand, introducing them into the blood while within the organism causes a generation of this substance, and a large increase of the bactericidal power of the whole of its blood. You see how this points to our having here to deal with a true righting force—one called into existence by the disturbance, yet contrary in its effect and acting to undo that which caused it.

A second way in which the blood becomes inhospitable to bacteria is that without directly killing them off it renders them helpless and inactive by agglutinating them together This also must be due to the generation of some in clumps. substances in the blood which appear to obey much the same laws as the bactericidal substances of which I have just spoken, and I should not have expressly referred to it were it not that it furnishes us with a striking proof that these substances are present and take a real part in the defence of the organism in actual disease. Everyone knows how insidious is an attack of typhoid fever-how it is characterised by the absence of all marked symptoms if we except variations of temperature. A sure method of diagnosing it in its early stages was sorely needed and one has been found.

A small quantity of the fluid part of the patient's blood is drawn off in a suitable tube and some living typhoid bacilli are added to it. If they agglutinate, the patient is suffering from typhoid fever. Nature has begun to generate the defensive substances against that bacillus which she would not have done had she not been first invaded by it. You learn of the attack by finding that the defence has begun, just as the inhabitants of a beleaguered fortress might first learn of an assault by hearing the sound of their own guns opening fire on the assailants.

I see no reason for doubting that both these types of defence have in the past been useful and perhaps indispensable in protecting the organism throughout its evolution. But it is almost impossible to estimate the extent of the service they render. They act automatically and get used up in so doing. No doubt they kill or incapacitate vast numbers of microbes and any progress the disease makes is due only to those that escape them. But the extent of the service they render remains unascertainable because there are no means of determining what would have been the condition of things if they had not been at work. But there is a third type of defence to which this does not apply and which—so far as I can judge from the evidence—has a far higher claim on our attention not only by reason of its universality and efficiency as used by Nature but because it is such that we can avail ourselves of its remedial power in the practical treatment of disease. To deal with it adequately I must say a few words more as to the constitution of the blood stream. We all know that the blood is not merely a fluid. It contains organisms in enormous numbers—viz., the red and white corpuscles. With the former we have nothing to do to-day. The latter, which number in man about 8000 in a cubic millimetre, are many times the size of any micro-organism with which we are dealing, but nevertheless by their power of altering their shape by elongating themselves they are able to pass freely about among the tissues of the body in every direction, not only in the blood stream but after leaving it. These corpuscles, though produced and living in the body and essential to its existence, enjoy in a sense independent life, and doubtless obey laws such as govern other life of the same amœboid character. We may expect them also to possess inherited tendencies derived from and suited to the habitat in which they live and in which their precursors must have lived throughout the ages that have elapsed since the organism first came into existence. Long-continued observation distributed over a very wide range of different forms of life has during the last 30 years established the fact that these white corpuscles form a sort of police of the body whose business it is to arrest foreign bodies that make their entrance, and either to prevent their gaining access into the blood or to remove them from it. On the introduction of foreign bodies-say, bacteria-into the body of an animal there usually ensues a flow of lymph to the spot which is quickly followed by an incursion of large numbers of these white blood corpuscles which seize upon and ingest the bacteria, and ultimately digest them, though slowly. If the number or avidity of these corpuscles is normally support the testimony of the opsonic index-

sufficient the infection is suppressed, but if from the number of the bacteria inoculated or the rapidity of their multiplication they are too much for the white blood corpuscles they establish their footing, and an infection ensues which may remain local or may become general according to the circumstances of the case and the nature of the bacteria. I need not, I think, apologise for thus briefly referring to these facts which must be familiar to most of you because I wish them to be before your minds while we deal with this part of the subject. They obviously explain how it is that we and other animals are immune to attacks of many kinds of bacteria which in themselves are fully capable of producing disease. It is not that the blood is unsuited to nourish them, for some of them will multiply rapidly when its serum is used as the cultivating medium. But if the white blood corpuscles are more than a match for them they can gain no footing in the body. Let me give an example. The frog succumbs rapidly to even small doses of the toxin generated by the cholera microbe. Yet it is immune to inoculations of those microbes because the zest and vigour with which its blood corpuscles attack them is such that they are devoured before they have time to generate the fatal toxin.

But the problem with which we have to deal is microbic disease, and the word disease implies that the microbes have been at the outset too strong for the defence and have secured a lodgment. What effect has this on the action of the white blood corpuscles? Countless experiments have established that its normal consequence is to increase the avidity with which each corpuscle attacks and devours that particular microbe while it produces no change in its behaviour to other microbes. But the strangest part of the story is that this is due to no change in the corpuscles themselves. Transferred to the serum of a normal man they show no such predilection for these special micro-organisms. change is in the fluid part of the blood in which they move and live and if white blood corpuscles be brought from a normal man into that same fluid they will show the same greed. It is the flavouring that effects it—their appetite for the microbes is increased because of the presence of the changed serum, just as the appetite of a small child for bread and butter is vastly greater than his appetite for dry bread.

Let me now turn to that which specially distinguishes this third mode of defence, and which has led alike to the recognition of its supreme importance in nature and to its use in actual practice. It is that we can measure rapidly and with substantial accuracy the effect it produces. Equal quantities of the bacteria are exposed to the action of equal numbers of white blood corpuscles for the same length of time in the one case in the presence of normal blood serum and in the other case in the presence of the blood serum of the patient. Slides are made of the results and stained, and under the microscope they show clearly the bacteria within the corpuscles which have ingested them, so that an average can be obtained of the number per corpuscle so ingested in each case. The ratio of these numbers (now known as the opsonic index) shows to what extent the patient's blood is more active in attacking the bacteria than is normal blood that is to say, to what extent it has been roused to the defence of the organism. In the case of the microbes that we recognise as sources of disease it is found that this ratio is normally raised by inoculations of the dead microbe, and this is the case whether the body of the patient is infected or not. We are justified, therefore, in thinking that, in the absence of exceptional circumstances, this is a form of defence of which Nature universally avails herself when such a microbe gains entrance into the body.

But how does this show the importance of the part it plays? To appreciate the proof of this you must study the history of its use in practical therapeutics. We all of us bow to the authority of experimental science. But when experiment has resulted in actual use in practical life the authority of the experience so acquired is yet higher. And for years past, primarily in England (which holds a proud position as pioneer in the use of this method) and subsequently in many parts of the world, patients suffering from microbic diseases have been treated by it and according to its indications. The all-important questions of the magnitude and frequency of the inoculations have been determined by the effect on the opsonic index, and often it is only by that index that the nature of the hidden foe has become known. Throughout this long trial it has been found that the clinical symptoms that when it is high the disease loses power and that when it sinks too low the disease makes progress. Such an accumulation of observations renders highly probable, though it does not absolutely demonstrate, that this is the main operative defence in the case of bacterial diseases. But it at all events demonstrates that for practical purposes we may take it to be so. The correspondence between the variations of the opsonic index and the clinical symptoms which can be obtained when experience has taught the proper dosage shows that even if we assume that other defensive forces of importance are present they must keep step with it, must vary as it varies, so that if we fix our eyes on its indications and act as though it alone existed we shall be following the right course, however many secret allies it has in its work.

But the success of this treatment of actual disease can

hardly be understood without the consideration of one difficulty which must, I am sure, have occurred to many of you in thinking over the theoretical explanation of its If the presence of bacteria thus increases the ferocity of attack of the white blood corpuscles, why is it necessary to introduce additional ones in the case of actual disease? In such a case the infection already exists; the microbes are already present in the system. Why do not those microbes operate to produce the desired effect? The use of the method to produce immunity against future attacks presents no such difficulty, because you there introduce the microbes into an organism that is free from them in order artificially to stimulate it to take up a position of active defence. But this explanation seems not to apply where similar microbes are already present. The true explanation of this apparent parodox is, I think, to be found in the mode of existence of the microbes when they have effected an entry into the body. Comparatively rarely do they succeed in maintaining themselves in the full blood stream. In the cases in which they do so (which are known as generalised infections) the battle is almost always short, sharp, and decisive. It would seem that the body cannot long tolerate such an intrusion by microbes, though the same cannot be said as to organisms of a somewhat higher type. In microbic diseases the microbes generally locate themselves in more or less clearly defined positions or foci of infection, and maintain themselves there with a certain degree of permanence. Such localised infections are so much more common than the general distribution of the bacteria throughout the system which is found in generalised infections that they may claim to be the normal

type.

Let us consider what goes on at such a focus. For the sake of clearness take the ordinary case of an infection by staphylococcus such as a boil. In it and along its borders the microbes abound so that they reign supreme. Nature for her own purposes has been desirous of cutting the part off from the general circulation, and has, for better or worse, succeeded to a great extent in so doing though perpetual frontier fights are still carried on. The effect of this is twofold. Nature reaps the benefit of isolating the invaders in their territory but it is at the cost of leaving it unswept by the blood stream so that the blood but little affects or is affected by what lies therein. The focus of infection constitutes a sort of Alsatia which the police leave unraided so long as its inhabitants keep within its borders. Such conditions contrast strikingly with those which are present when an inoculation is made. The microbes are there introduced into healthy tissue and in moderate numbers. They are not living microbes and so cannot possibly resist the attacks of the white blood corpuscles. If the actual generation of the protective substances takes place in the tissues they are surrounded by tissues in their normal and healthy state; if it takes place in the blood they are in free contact with it. That they should produce effects which the microbes in a focus of infection fail to produce ceases to be difficult to understand. It is an undoubted fact that they do so, inasmuch as otherwise it would be impossible to effect anything by inoculations. We should have to rest content with the results of the automatic action of Nature. We could neither strengthen nor assist it. Perhaps at first sight the fact that the microbes in the inoculations are dead would seem to make a difficulty in understanding their being so effective. But this only means that Nature recognises her minute foes by the taste of their flesh. These defensive reactions have been slowly evolved throughout long ages when the presence of microbes—alive or dead—

could only be due to an invasion, and it is no wonder, therefore, that the sudden appearance of a considerable quantity of them-whatever be their state of vitality-should be considered by the organism as a sufficient warning that it is time to call forth the forces of defence. When the inoculation has succeeded in midtion has succeeded in raising the avidity of the white blood corpuscles it is easy to see what happens at the focus of infection. The sulky and ill-kept truce is no longer observed. The corpuscles are able successfully to penetrate farther across the boundary because they can dispose of so many more of its defenders. Gradually the ground is cleared and the focus diminishes in size, and if the reaction to the inoculation be adequate and sufficiently long sustained the infection wholly disappears. Such a result is a matter of daily experience with staphylococcus in boils and carbuncles, with streptococcus in erysipelas and abscesses, with tubercle in glands, joints, and the other localised forms which used to be known as scrofula and in many other cases. The list of successes is a long one-far too long to be given here-and I am convinced that to make it many times as long only needs more workers in the field.

In thus giving my interpretation of the successes of inoculation in localised infections it must not be thought that I limit it to cases where definite foci exist. Analogous protection is doubtless found by microbes that affect special membranes or special organs and the structural changes which they cause may assist in sheltering them from the blood stream. Nor do I wish to imply that the treatment may not ultimately be made serviceable in generalised infections. But up to now its most marked and most uniform success has been in cases where the microbes have become more or less permanent inmates of the body.

It is the discovery that inoculations of dead microbes will increase the avidity with which white blood corpuscles attack microbes already present in the system which has lifted up therapeutic inoculation and has assigned to it a far more important and useful sphere of action than that which the earlier work indicated. That earlier work only aimed at rendering organisms immune to special bacteria and the memory of those early days has caused the term immunisation to cling to the whole subject of treatment by this type of inoculations. I regret it because it gives a false idea of what is now its true aim. It seeks to defend you against actual present enemies and not against possible future ones. You remember the legend that has been handed down to us about Mithridates, that he had so soaked himself in antidotes of all kinds that no poison could affect him. It would be no very exalted aim to seek to make a world of modern Mithridates, even if it were possible. Moreover, it would be a formidable task because we have learnt that these defences are strictly specific—each protects against the one microbe and no other-so that general immunity could only be obtained by countless inoculations even if the poor tormented body could bear them. It is a much more worthy task to defeat and drive out an enemy that is actually in the field. In such a case we fight only the evils which actually exist and not all possible forms that may or may not exist in the future. In such work the fact that the defence is specific helps rather than hinders us. The cultures can if necessary be made from the invading microbe itself, so that there can be no error in identification, and the importance of certainty in this respect is crucial. How absolutely indifferent microbes are to anything not directed specifically against them is well illustrated by a case of which I learnt a short while ago, where the patient was suffering from tuberculous glands. Treatment with tubercle inoculations healed them completely with the exception of one which continued unaffected until at last it commenced to suppurate. It was then found that the mischief in that gland was due to the presence of a streptococcus. Cultures were made from it, and in its turn that gland also healed up under treatment with inoculations of those cultures. It yielded when the treatment was specifically adapted to it, though it had been utterly unaffected by the previous inoculations.

This subject should therefore, in my opinion, be studied as a curative and not as an immunisating treatment. If I may use such a word it is phylactic and not pro-phylactic inoculation that we need. When we know that immunity of a high order against an ordinary disease can be obtained with little trouble, or when we know that an individual will shortly be exposed to special danger of a known kind, as, for instance, where troops are to be sent into districts infected

with plague or typhoid fever, it is doubtless wise to take precautionary measures. But these may be looked upon as special cases, while the domain of inoculation as a curative agent is well-nigh as wide as disease itself. It thus offers an almost boundless field for study. The fundamental laws on which it rests have been established and rules guiding its practical use have been laid down. But the conditions under which it works best in each case and the most desirable accessory treatment are to a large extent unstudied. that some of those whom I am now addressing will help in these respects to advance our knowledge and enable mankind still better to conjure with Nature's own spells.

Let me now shortly sum up the record of the last forty years as I have presented it. Science began by teaching us that we live as it were immersed in a sea of minute life; that micro-organisms are all around and upon and within us; that they are to be found not only in air and in water but upon almost everything that we touch; that while some are harmless and possibly beneficial to us, some are our deadly **en**emies. It has since convinced us that all infectious diseases as well as many that are non-infectious are due to these microbes; indeed, that there are few diseases which are not either originally caused or at some later period in their course aggravated by their presence. Life is one ceaseless war against these enemies, and the periods of our too transient successes are known as health. This condition of constant and deadly strife not only obtains during our own short lives but must have equally obtained throughout the long line of development of which we are the result. Yet the victory has not rested wholly with our foes. Our very existence is proof that Nature has at all events learnt how to conquer so far as she needs—i.e., she has not let the individual succumb too early for the continuance of the race.

We have seen how formidable her task is. She cannot effect it by isolation, for we derive our sustenance from without. The need of breath and nourishment compels free intercommunication with the external world, and we must accept its attendant microbic dangers. The choice within is equally fettered. In the life of nations the arts of peace on which the existence of the people depends must be paramount. War is only accessory to them-to assure the possibility of their continuance. Just so in the organism the task of nourishing the cells of the body stands first. It must be performed at all costs and at all risks. She must defend the organism under the conditions of an uninterrupted flow everywhere of a fluid of the highest nutritious value capable of satisfying all the wants of varied and highly specialised cells. And if nutritious to the cells it must be liable to become food to microbes who have had to maintain their existence amid all sorts of environments unpampered by such delicate nursing.

Our examination has shown to us three main characteristics of Nature's solution of the problem. In the first place, we find that she chooses the blood stream as the seat of the defence. Nothing less than this universal environment suffices because the mischief is equally wide. In the second place, we find that the defence is specific—it is directed in each case against the particular assailant and no other. In the third place, we find that in the intervals of the attacks the defence lies in capacities, not, if I may use such a term, in actualities. In other words, it is the presence of the enemy that calls into existence the changes in the blood stream that repel him, and those changes are antagonistic only to that special enemy. We have also seen that her task is twofold. The microbes generate toxins which will poison the organism if not neutralised and the microbes themselves will multiply to a fatal extent if they be not exterminated or at least kept down. Her defence against the first of these dangers is the generation in the blood of a specific antidote to the specific poison. Her answer to the second is manifold but it again is in the form of the generation of defensive substances in the blood. Sometimes the defensive substances are poisonous to the specific microbe, sometimes they cripple though they do not kill. But the defence upon which she seems above all to rely is the generation in the blood stream of substances which make the watchful white blood corpuscles devour that particular microbe with a greater zest until not even its tremendous powers of multiplication can save it from destruction.

In all this we see the action of righting forces-forces that come into operation when the organism is disturbed and for you will have learnt to follow her tactics.

tend to restore it to its normal position of equilibrium. In the case of the ship to which I have made reference engineers will demonstrate to you that the stability is given by the action of gravity on the supporting water. But what can be the mechanism here by which it is brought about that the poison generates instead of exhausting its antidote, and that the presence of the microbe leads to the production of a suitable condiment, and thus stimulates instead of satiating the appetite to devour it? To that I can unhesitatingly give the answer-I do not know. And for myself, I might put it in the yet stronger form—I have not the slightest idea. To me the mechanism that underlies these paradoxical manifestations of life is an absolute enigma. I accept them as fundamental laws because experiment has demonstrated their existence. But it has not lessened their mystery. I am aware of the brilliant scientific hypotheses which have been devised to ease somewhat the burden of belief, and I recognise the service they have rendered to investigators while groping their way in the present half light of early dawn. But I would utter a note of warning in their regard. Do not confuse the facts which are learnt by experiment with the hypotheses which are designed to explain them. The former cannot pass away, the latter may have to be abandoned in the fuller light of future knowledge. So long as a suggested mechanism accounts only for the phenomena which gave rise to it, it can only claim to be regarded as a possible solution of the riddle. It is when such a mechanism is found to account also for other phenomena widely different from those that suggested it that it first becomes entitled to claim to be regarded as the actual solution. I reconcile myself to the belief in these mysterious responses of Nature, not by speculations which would lessen their apparent strangeness, but by the reflection that life itself is so mysterious, so inexplicable, that one ought not to wonder that it can only exist by reason of reactions themselves inexplicable. I do not doubt that the part played by micro-organisms in the early days of the existence of life was as important and as universal as it is to-day, and the need of an adequate defence against them must have been a primal difficulty in the path of evolution. In experimentally isolating these laws we are bringing ourselves face to face with the special features of the solution that was found, and, strange though they may be, I do not feel impelled on that account to reject them when I realise that the incorporation into vital structure of some mechanism which would thus provide an automatic system of defence against microbic life must from the first have been a condition precedent of further advance.

Finally, I have called attention to the curative power that the new knowledge places in man's hand. In cases such as diphtheria and tetanus, where the poison is so powerful and so rapidly generated that it constitutes the main danger, we can gain for Nature the time necessary for calling her defensive forces into play by introducing from without supplies of the antidote which she herself has generated abundantly under more favourable circumstances. specific danger threatens in the near future we can by sterile inoculations into the organism while as yet unattacked rouse into actual operation its latent capacities for defence, so that if the attack should come it will find them in full play. But above all in that type of microbic disease from which humanity most frequently suffers, where the micro-organisms have located themselves so as to be more or less sheltered from the operation of the blood stream, and thus to avoid rousing its powers of antagonism, we can by like means stimulate the white blood corpuscles of the whole organism to fiercer attack, and as long clinical experience has already shown can little by little drive out the enemy from the position in which it had entrenched itself. In all this we are adopting Nature's means in order to outdo her work. For you who in the future will exercise the high calling of a doctor must never forget that you have set youself a harder task than that with which Nature contents herself. sacredness of human life in our eyes compels us to keep alive those that Nature would let die—to produce health where she would accept disease—to make life possible under circumstances where she would abandon the attempt. She is satisfied if the efficacy of her defence would save enough. We seek to save all. But though you seek thus to outdo Nature you cannot effect that object better than by wisely supplementing according to individual need that which is done automatically by Nature in racial self-defence. In so doing you will be a useful ally to Nature and fit to fight by her side,

Abstracts

OF

INTRODUCTORY ADDRESSES, ETC.,

DELIVERED AT THE

MEDICAL SCHOOLS

AT THE

Opening of the Session 1909-10.

ST. MARY'S HOSPITAL MEDICAL SCHOOL.

INTRODUCTORY ADDRESS BY H. A. MIERS, D.SC., F.R.S., PRINCIPAL OF THE UNIVERSITY OF LONDON.

Dr. Miers took for his subject "Theories." After a few introductory words he said: Those who possess the rare gift of originality belong to the genus of poets or makers of thought; they can be safely trusted to make something new however often they may be called upon. But it has sometimes seemed to me that though there are comparatively so few who possess this great faculty, it is at the same time true that there is for all people a certain period of life at which they are ready and anxious to invent and to produce something original, something of their own making, and that at this period they generally try to do so, however ineffectual may be the result. It is in the period including the close of school life and the beginning of university life, or whatever comes after school, that most people have been guilty of attempts to write poetry, or have endeavoured to construct a tale, or have believed themselves to be on the brink of a discovery or invention, or have taken up some new idea or theory of life which is, for them at least, a new thing of their own making and a piece of their own philosophy. I do not forget that many of those whom I am addressing are living in this happy and fruitful period. It has been too much the fashion to decry youthful efforts and to endeavour to persuade ourselves that knowledge and experience are required before anything good comes out of a man unless he be a heaven-born genius. For my part, I believe this to be really the productive period of an ordinary man's life, and that he who takes the trouble to search the history of his own mental development will find that anything which is the unaided product of his own intellect dates from this period; that the germ of any original thought which finds its expression in his more mature life is to be traced to late boyhood or early manhood. It is surprising how many authors have delivered their message and have said what they really have to say in their first, or at any rate in an early, book, perhaps so crudely and ineffectively that it has failed to catch the popular attention; it may be only with improved style and knowledge and experience that they have secured an effective hearing. Yet for all that, the later writings have been only developments of the original idea or variations upon the same theme.

Mentally as well as physically the child is father of the man, and it is generally possible to trace any person's original ideas to that early productive period, just as it is possible to find the features of the man in those of the child. The powers of expression may develop, new impressions are received, new ideas are acquired, but the original ideas of that period persist and are a part of one's nature, in a sense quite different from that of anything that comes later; they can never be completely shed, their imprint is permanent. It is something like the effect of the books which are read in childhood: their impression is never effaced, throughout life we regard them with feelings different from those which are stirred by the books that came later, and our childish regard for them persists in spite of our better judgment. But there is this difference between the impressions of childhood and those of manhood: the intellectual events of childhood came from without, and were most deeply impressed because that was the most impressionable period of our life. but the intellectual events of the later epoch of which I am speaking came from within and belong to the creative period. People, of course, change their views, give up the old and take on new ideas, but I believe that you will find that the new ideas which come in later life are generally adopted from others, often consciously adopted, and that the struggle adoption are due to the fact that they come from without and that a great battle must ensue before they can dislodge that which is really part of ourselves and not consciously derived elsewhere. Left to itself the mind revisits the early haunts, and continual effort is necessary to prevent a return to the thought which originated in that brief creative period.

There are two reasons why I venture to make these apparently inappropriate remarks. The first is, that after a certain age it is not profitable to try to be original; one has no new message to deliver; one must borrow a message from some wiser person or say something that one either said or might have said 20 or 30 years ago. And the other reason is, that in addressing students one is addressing those who are at the most original, inventive, and creative stage of their existence, and it is much better that they should develop their own ideas and foster the offspring of their own brains than adopt the thoughts of others. There is also, perhaps, another reason why I propose to dwell for a while on this subject. At the present time, when education is becoming more and more highly organised, there is a tendency to insist more and more upon the necessity of preparation. Before you can begin one subject you are told that you must master another, and a great part of our life is occupied in preparation for something else; indeed, there are people who, not only in their student days but through their whole life, are so much overwhelmed by the necessity of preparation that they spend it in preparing for things that are never done, endeavouring to master the ideas of others before daring to have ideas of their own, and pass an existence of promise without ever attaining to performance. It is quite clear that if you never undertake anything until you are fully and completely prepared you will not get very far. Considering that all school life is devoted to preparation, one would think that after school days the time had arrived to do some of the things for which one has been qualifying oneself and to develop one's own ideas.

There are some theories of education which are rarely stated as such by their adherents, but which none the less dominate their methods of teaching. For example, the view that it is a sound policy to teach things which are distasteful to the pupil because it requires a greater mental effort on his part to acquire them and is therefore a better training. Or the view that early or even university education is better devoted to teaching things that are never likely to be any direct use to the student than those which will be required by him in his life's work, because the latter are certain to be acquired later in the exercise of his profession or calling; and to teach them savours of technical training and is not education. In the last generation such views were openly expressed, and at the present day they are often at the back of a teacher's mind. They entirely ignore the incalculable value of enthusiasm in one's work, and forget that effort exercised upon something that awakens the interest of the pupil is far more profitable than the forced effort which is unaccompanied by interest. This was the fault of the old-fashioned classical training, or rather of the old-fashioned methods of classical training. It was all very well for the boy with literary instincts and tastes, but for the ordinary boy it was a study which had no point of contact with real life, and was only a task. The very language into which the classics were translated was not English, but the uncouth and hybrid tongue of the "crib." The literary methods of modern teachers, the living discoveries of archæology and philology have changed all this, and a boy or girl who reads. Professor Gilbert Murray's translation of or girl who reads Professor Gilbert Murray's translation of Euripides cannot any longer regard the Greek language and literature as a lifeless or barbaric thing. Another educational theory similar to these is the view that you ought to be always amassing a knowledge of facts not for present but for future use. Persons brought up in this spirit, or who of themselves prefer to work in this spirit, not only lose all the present interest in the vitality of their work, but live for the rest of their lives in a continual state of expectation or preparation, and are again investing their intellectual resources in promise instead of in performance. Let us rather be up and begin the work of life.

> Dimidium facti qui coepit habet : sapere aude : Incipe. Qui recte vivendi prorogat horam Rusticus exspectat dum defluat amnis : at ille Labitur et labetur in omne volubilis aevum."

from others, often consciously adopted, and that the struggle Or let me recall the words in which Carlyle speaks his heart and intellectual turmoil which so often accompany their in the book which contains his message to mankind, the

words that close the wonderful chapter in which that message is really contained:—

I too could now say to myself: Be no longer a Chaos, but a World or even Worldkin. Produce! Produce! Were it but the pitifullest infinitestimal fraction of a Product, produce it, in God's name! The the utmost thou hast in thee: out with it then. Up! Up! Whatsover thy hand findeth to do, do it with thy whole might. Work while it is called to-day: for the night cometh, wherein no man can work.

If there is a time of life at which these words may be taken to heart it is surely that which I have called the creative or productive period, and it will be sad if any of our educational methods or practices tend to stifle the creative or

productive power at this critical period.

I must not forget, however, that I am addressing those who are about to devote their lives to the profession of medicine, and that if I have anything to say it must be applicable to the medical student, or I shall not be able to justify my acceptance of your invitation to-day. Well, I think there are two reasons why the line of thought that I am suggesting should be of some profit to medical students. The first is, that, taken as a whole, there are, I believe, no students who are more keen upon their work or take more pleasure in it than medical students, so that they are not likely to be deterred from original thought by lack of interest. There are not many of them to whom their work is merely an educational task: a man rarely becomes a doctor or surgeon unless he feels some call to the profession, and he is generally working, not against his inclination, but in accordance with it. I do not think there is any other professional training of which this is equally true. And the other reason is, that in no profession is preparation more necessary or more arduous than in yours; no other man has to master so many preliminary subjects or spend so much time in fitting himself for his profession by scientific preparation. If the one circumstance is all in favour of intellectual activity and interest, the other seems to be all against it. wish, if I can, to show how they are to be reconciled.

There is a fable of Æsop quoted by Francis Bacon in his "Advancement of Learning" in connexion with alchemy. Let me tell it to you in his own charming words:—

Surely to Alchemy this right is due, that it may be compared to the husbandman whereof Æsop makes the fable; that when he died told his sons that he had left unto them gold buried underground in his vineyard; and they digged all over the ground, and gold they found none; but by reason of their stirring and digging the mould about the roots of their vines they had a great vintage the year following. So assuredly the search and stir to make gold hath brought to light a great number of good and fruitful inventions and experiments as well for the disclosing of nature as for the use of man's life.

I desire to bring home to you the lesson of this fable, that an idea, a theory, may give the necessary impulse and may inspire the enthusiasm that leads to good work, even though it be itself an insufficient or even an incorrect theory; for, after all, we have generally to be content with a working hypothesis, and the best of our scientific theories is liable to be overturned and will have to give place to a better. But that is no reason why we should not believe in it and be led by its inspiration. To the greater part of mankind such impulse is necessary, and the work of life without faith in some principle loses its inspiration and its pleasure. wish to believe that our labours lead to some result and that our knowledge is dominated by some principle, and we like to persuade ourselves that we know what it is. There are, it is true, rare spirits, like Browning's grammarian, "decided not to live but know," scholars and students of sincere and simple character, who are content to labour in the wide faith that earnest toil is bound to lead to useful results, and are content with the life of preparation.

"This in him was the peculiar grace— That before living he'd learn how to live— No end to learning."

But not many of us are scholars of this mediæval and cloistered type—

"Only to ourselves proposing problems proper to be solved By ourselves alone—who working ne'er shall know if work bear fruit Others reap and garner, heedless how produced by stalk and root;"

and least of all are they to be found in such an active profession as yours; great scholars, sometimes great teachers, may be made of such material, but not, I think, great doctors.

You in your more active life need the inspiration of a theory, the illumination of an idea, which can glorify the drudgery of preliminary studies, and the details of ordinary practice. That is the spirit of modern scientific work: the

restless desire to prove or to demolish the theory on which we are working for the moment and to discover the principles which underlie all that we can observe or do. It is this faith in a principle, this hope that we shall discover it, this certainty that our theory is leading us on the way to its discovery, that gives to even the drudgery of scientific routine work such a fascination for those who have once tasted the delight of scientific research. Work illuminated by a theory, or carried on with a general principle in view, cannot fail to be interesting, even though it be only work required for preliminary examinations. The moral that I wish to draw from the fable of Æsop for my present purpose is this: In all your work have a theory and believe in it, let it be your own if possible now in the creative and inventive period of your life; test it, not by the opinions of others or by their knowledge, but by your own observation and your own experience. No matter if you have later to reject it. Work uninspired by an idea is as aimless as a life uninspired by principles. The idea, especially if it is one's own idea, lends an interest and an excitement to scientific work, and, indeed, to all work, and, like the wishing cap of Fortunatus, transports its owner to a new world.

To Charles Darwin every little event, every trifling observation viewed by his thoughtful mind and in the light of his far-reaching theory must have been invested with an equal and an overwhelming interest; to his eyes every little detail must have had a significance which it possessed for no other. Let me remark in passing that Francis Darwin, in his introduction to the recently discovered sketch of the "Origin of Species" written in 1842, shows good reason to believe that the theory was budding in his father's mind when he was only 23 years old. Newton was only 24 when his conception of universal gravitation first found expression. Pasteur was about the same age when his mind was occupied with the theory of the relation between the disymmetry of crystals and the processes of life. Young had developed his theory of the interference of light at the age of 27. Galileo made his great discovery when he was 19. By many other examples I could justify my suggestion that the original idea or its germ in scientific thought, as in other subjects, is to be found in this productive period of early manhood. This is why I urge you to make and test your theories now and to turn a deaf ear to those who say that you should not begin to theorise until you have acquired knowledge and experience. Surely knowledge and experience are of use for the testing of theories and not for the making of them.

Let it be understood that I find no fault with the industrious accumulation of facts, with the patient study of details, at any or every period of a career. Did not Darwin himself supply the best possible illustration of this feature of the best scientific work? I would only ask you to remember that it was the theory which made those facts and details the most interesting things in the world to him, and it was because his course was illuminated by the guiding light of a theory that it led to such remarkable results. this it was by no means necessary that the theory should be a right one. In his autobiography, after saying that from early youth he always had the strongest desire to group facts under some general laws, he says: "I have steadily endeavoured to keep my mind free to give up any hypothesis, however much beloved (and I cannot resist forming one on every subject), as soon as facts are shown to be opposed to it. With the exception of the Coral Reefs, I cannot remember a single first-formed hypothesis which had not, after a time, to be given up or greatly modified." There is to many, if not to most, minds a peculiar pleasure in the mere amassing of facts or the mere acquisition of knowledge, but this is not the pleasure of higher scientific work; it may lead to a species of intellectual miserhood, and corresponds to the acquisitive instinct of a man who is a mere collector and whose pleasure is only in the possession of rare things and not in their use. It is sad to think that, whereas the collector of art or other treasures may perform a very useful function in the world by bringing together objects that would otherwise have been scattered or lost, the knowledge which the intellectual miser has collected dies with him and cannot even be bequeathed.

Again, there is a certain pleasure in the making of observation—in the mere exercise of the faculties involved in the process. It is delightful to contemplate lazily the

P 2

breakers rolling in upon a sea beach; but let yourself begin to wonder whether the belief of the Greeks that the TRIKUMIa or every third wave is the largest, or that of the Romans that they recur at the fluctus decumanus or tenth, is the more true, and you will find yourself looking at them with closer attention and a new interest. Even so is there an added interest and an increased pleasure in any observation which is made not aimlessly but in the light of a theory. If you analyse the feeling I think you will find that it is due to the expectation; it is part of our sporting instinct, and is the same spirit which makes it interesting to watch the movements of the bird or beast or fish that we are hunting or to follow the varying fortunes of a game. The expectation is aroused and the attention is arrested. This sort of excitement is quite different from that of a very young child whose interest in everything is intense, but is aroused by one thing after another and not by the expectation of what is to come; his mind is not yet capable of that imaginative and intellectual effort. It is curious to watch a very small boy even learning to play cricket or football; he cannot keep up his interest, but gets distracted by other things that catch his eye; "atque animum nunc huc celerem nunc dividit illuc." It is a mistake to expect children of this age to find much interest in a theory or in first principles, as some educational authorities would wish. But it is just as much a mistake to expect university students to devote their thought and their energies to the provident but blind acquisition of knowledge for some unknown future use as the ant stores its provender for the winter. The real but aimless delight which is excited by the mere exercise of our faculties, whether in learning or in observation, is a sort of sensual pleasure, and I would contend that it is a very different thing from the intellectual pleasure of scientific discovery; and when the child's power of acquisition, which is due to the pleasing exercise of the marvellous memory that all children possess, is beginning to fail it is time that the higher intellectual powers should be developed.

You will understand, I hope, what I am driving at: it is, that after school days are over all the preparatory and educational work that we have to do should be taught and learnt in a new spirit, no longer as an exercise or a preparation, but as real active, living research guided by the light of theory and inspired with the hope of discovery. A great fault of the unsatisfactory, though necessary, examination system is that it tests the quality of memory unduly and can never do full justice to the other mental faculties, and so it inevitably encourages an uninteresting and uninspiring style of study. Surely to no one is the encouragement of the research spirit more necessary than to the medical student, who has to learn so many subjects and to pass so many examinations before he can get to the work of his life.

There are two ways of carrying on work in the spirit of research—one of them is to work in the constant and lively expectation of something new turning up without knowing what it will be, or rather in the confident knowledge that if we keep our eyes open we shall most certainly see something new in the most ordinary and oft-repeated laboratory exercises. And the other is to be always working in the light of a theory—in other words, to know what we expect and to test this expectation. The first method cultivates alertness of interest and observation. The second method is best suited for special and more advanced studies: it cultivates intelligent thought. And that is why I counsel medical students in all their work to adopt a theory and stick to it as long as they are able, and then, if necessary, to invent a new one, to work in the spirit of investigation in the light of their theories.

If you say that it is not so easy to invent a theory until you have mastered a subject, I would reply that every time you try to understand an experiment, an observation, indeed anything before it has been explained to you, so often are you obliged to invent an explanation or theory of your own: and that is all that I ask, neither leave the facts without an explanation of your own nor accept the explanation of another without thinking what it means. Perhaps if I were to counsel the other method and beg you to be always trying new things on the chance of a discovery and without understanding them I should lay myself open to the charge of advising medical students to experiment on their patients. a charge which is already made by the suspicious minds of too many ignorant persons. Let me, however, guard myself by reminding you that I am speaking, not of clinical practice, of which I know nothing, but of the learning and

teaching of science, of which I have some general knowledge.

Often must the medical student ask himself with a groan why he is expected to devote so much time to chemistry and physics and mathematics, which will apparently be useless to him in the future. If he really has this feeling I think it is due, not only to the narrowness of his own view, but partly, perhaps, to the very zeal and excellence of the teachers of these preliminary subjects. A mathematician teaches his subject as though all his pupils wished to become mathematicians, a chemist as though they wished to become chemists, and so on; and the text-books are written in the same spirit. So that the medical student runs, perhaps, a greater risk than any other of having his interest deadened by these preliminary subjects at the very time when his mind is most on the alert for new ideas. And yet, of course, these preparatory subjects are absolutely necessary; whether they are also interesting is, I think, entirely a question of how they are regarded. If properly taught and properly studied they ought to be not chemistry or physics or mathematics, but the chemical or physical or mathematical aspects of his own well-loved medical science; illustrations of the principles of that science, the materials and the tools by which its theories can be tested. Every student is most keen upon some special subject. Well, so far is science from being separated into water-tight compartments that I believe there is no branch of science which cannot be taught to him and made interesting to him through his special subject.

It would, no doubt, be very satisfactory if every medical man could have been first a mathematician, then a physicist, then a chemist, and so on through the different stages until he finally became a doctor. But life is not long enough for this process, and the minds of ordinary men are not able to contain so much knowledge. Helmholtz, who almost alone among men possessed the necessary mental powers, curiously pursued the opposite course, and, having begun as a military surgeon and then teacher of anatomy, became successively professor of pathology, anatomy, physiology, and physics. But his career really illustrates what I have been saying, for through his early interest in physiology he was led to make himself the first physicist in Europe, because you cannot be a first-rate physiologist without being a physicist; and on the way he made himself one of the first mathematicians in Europe, because you cannot be a first-rate physicist without being a mathematician. When he was asked to take up the Chair of Physics and Mathematics in Bonn he replied: "In lectures on mathematical physics I should treat mathematics as the means and not as the end. Wherever possible I should include the physiology of the eye and ear." Later in life he said: "I have always been aware, and have often said expressly, that I owe much to the study of medicine even in regard to my later career as a physicist. It gave me a much wider knowledge of Nature than I could otherwise have obtained from studies limited to inorganic nature and to mathematics: and the grave responsibilities that devolve upon the physician to ensure the success of his professional treatment accustomed me at an earlier period to strive after an exact knowledge of the actual facts and their consequence." Although we are not likely in the course of many generations to encounter another Helmholtz, we may at any rate remember from his example that there is no need to cut up the sciences into isolated compartments. Indeed, when you begin to reflect upon any theory, or law of Nature, or general principle, you at once cross the boundaries between the sciences.

If you read the history of the great discoverers, or of those who have made any successful advance in science, you will find that this is the spirit by which they were animated in their student days—the determination to understand what they learnt by getting a grasp of general principles, to put an idea of their own into it, and so to get something new out of it. Herein is the great charm of scientific work: in every observation or experiment, timeworn exercise though it may be, there is something new to be seen, some discovery to be made by those who have eyes to see it, and an idea to guide them. To such a person they can never be mere exercises, they are a field of unknown possibilities. I suppose there is no science in which these possibilities are more abundant than in yours; so, in spite of my ignorance of the principles of medicine, I have no hesitation in asserting again that the student who can work, however humbly, in the spirit which animated Darwin in

his young days, is certain to find an intellectual interest that cannot otherwise be acquired, and is certain to be rewarded by some advance or discovery, some new fact, or some new thought, that will be a full compensation for any labour that he may have incurred.

CHARING CROSS HOSPITAL MEDICAL SCHOOL.

INAUGURAL ADDRESS BY SIR T. CLIFFORD ALLBUTT, K.C.B., M.D., F.R.C.P. LOND., ETC., REGIUS PROFESSOR OF PHYSIC IN THE UNIVERSITY OF CAMBRIDGE.

AFTER presenting the scholarships, medals, prizes, and certificates to the successful students Sir Clifford Allbutt addressed the students. He discussed two topics-the importance of athletic games in the formation of character and the advantages of anatomy as a disciplinary study. He said it always gave him great pleasure to be present at a prize-giving ceremony. As regarded students who had won prizes he did not consider that their success would do them much harm, while those who had lost would get great benefit, though this benefit might be an indirect one. In life we all lost many prizes which we much desired, and it was well that no man should enter the battlefield of life without a little experience of disappointments. Men were very frequently apt to think that they had been overlooked when they failed to obtain some coveted appointment, and were sometimes inclined to believe that they could fulfil that appointment better than the man to whom it had fallen. We should understand that throughout the whole of life we must be prepared to receive set-backs, and by learning that lesson those who failed to get a prize in their student days might reap a greater benefit than those who won the prizes. On such occasions as the present, although there must be a great many men who were disappointed, there was one very striking feature in all British schools-namely, the entire absence of the very slightest shade of jealousy. It was very interesting to notice the cordial way in which those who were unsuccessful gladly and even enthusiastically welcomed the success of their comrades, and it was a pleasant fact that the enthusiasm even increased when the same student received more than one distinction. If the disappointment which resulted from the unsuccessful effort to win a prize was the best possible preparation for entry into life, yet the disappointment must be taken in a buoyant way and without the smallest touch of jealousy. This characteristic was the result very largely of our British games. He was not one of those who joined in the outcry against athletic games, for they engendered the virtues for which he was contending. By such games we learned the proper spirit in which to take little rebuffs and pains, and to subordinate our own opinions to the ruling of a captain, and to obey orders without hesitation and without recrimination. All these "drills" were exceedingly valuable, and it would be a very great misfortune if games fell out of fashion, or if, on the other hand, we paid other people to play our games for us. By means of games the education of character should go hand in hand with other studies. He noticed that the men who won prizes in school were very often the leaders in the playing fields. By the practice of games in a way which no gymnastics could supply we learnt to take the ups and downs and the chastisements of daily life. For life was a game, and it was in his student days that a man learned to play that game also properly. Even in games there was a great deal of drudgery, and we must not suppose that in the higher game of life or in school drudgery would have no place. Some teachers thought that it was possible for students to learn without drudgery. In modern education there was a tendency to represent education too pleasantly. Although it was possible to make the learning of some branches of science easy and even amusing, there were stages of learning which required much drudgery and a considerable amount of self-control. Many students came up to the universities who, although clever in many directions, had not learned to drudge, and were consequently without the capacity for precise study which the acquisition of true knowledge required. Recently the subject of anatomy had been much discussed as part of that great question of the curriculum of the medical student. The question of the curriculum was, indeed, a most difficult one to adjust. Almost every term he had complaints from specialists that a man had passed through the university who was unable, for example, to observe satis-

factorily the interior of a patient's nose. Yet, important as were all branches of medicine, he did not think that more could be got into the curriculum than it contained at present. Indeed, it astonished him that students were able to acquire the pile of knowledge which they seemed to possess in the five years of their study. And many who realised this heavy pressure on the curriculum wished to soften down the anatomy. What was the use, they said, of learning minute topographical details which would afterwards be of no practical service? His answer was that anatomy was, for its own sake, a disciplinary study of the utmost possible value. He knew of no study which forced upon the student the habit of close observation and the accurate representation of his subject as did anatomy. Even of graduates too many did not know what absolute precision meant. It was only after one or two subjects had been learnt profoundly that for breadth of view some other subjects might be learned more cursorily. Anatomy should be one of those subjects. The education of the physician was unique. No other came up to its standard of excellence. The physician was educated on a scientific basis, but his vocation afterwards involved large and wide moral issues as important to the patient as to the physician himself. All the new social problems were medical questions. He need not speak of them in detail, but did the House of Commons know what it was doing when it passed the law about the inspection of school children? Not in the least. But it had made one of the greatest steps towards social amelioration that had been made of recent years. The naval and military services of the country and the law were now organised on a great scale. The medical profession had to begin its public organisation. From being a private service it had now to become the great organ of growth in the State. Before very long the medical profession must be endowed with a ministry; it must have a hierarchy; it must have a means of expression and a defined responsibility before the public. "Make use of your time," Sir Clifford Allbutt concluded, "to take up the task before you."

UNIVERSITY OF BRISTOL.

INTRODUCTORY ADDRESS BY SIR ISAMBARD OWEN, M.A., M.D. CANTAB., F.R.C.P. LOND., VICE-CHANCELLOR OF THE UNIVERSITY.

THE first session of the University opened on Thursday. Sept. 30th, when the inaugural address was delivered by the newly appointed Vice-Chancellor, Sir Isambard Owen. large hall of the University was packed, many persons being obliged to stand. The chair was taken by Mr. P. J. Wasley. and there were also on the platform the Lord Mayor, the Sheriff, the Bishop of Bristol, Professor Lloyd Morgan (the ex-Vice-Chancellor), the Deans of Faculty, the Senate and Boards of Faculty, and certain members of the Council. Sir Isambard Owen, who was greeted with loud cheering on rising to give his address, congratulated Bristol on its accession to the ranks of the University cities. All honour, he said, to those who had toiled for this end, to those wealthy citizens who had made it possible, and to the corporation of Bristol whose foresight showed them what must eventually make for the welfare of the city. The nineteenth century was marked by a world-wide movement forward in higher education, which had brought the universities of both continents to a much fuller development than a hundred years ago. What was the significance of the modern university? The speaker answered his question by referring to the history and evolution of the university movement. It originated in the latter part of the twelfth century, in Paris particularly, where teachers and scholars of all nationalities resorted for the study of all branches of knowledge, and bound themselves together by mutual oath into a corporation comparable to the craftsmen's guilds of the same period. This compact corporation was not formed immediately, but by the aggregation of smaller corporations representing the various faculties; the Faculty of Arts contained several separate bodies or "nationalities" within itself which at first maintained an independent existence. The very word "university" was mediæval Latin for a corporation, and was equally applied in its earliest meaning to a barbers' guild. The teachers who constituted the corporation reserved the right of admitting others to the privileges of membership; those who were admitted were known in some universities as masters, in others as doctors, in others, again, as professors. These titles, each of which now has its

particular meaning, were once interchangeable and expressed the same idea with a variation of local colouring. The bachelor of the ancient university was not a full member but a kind of pupil-teacher. The object of such a corporation was not primarily the advancement of learning but the protection of the privilege of teaching. It came to pass, however, that those who were so imbued with the love of knowledge as to desire to teach it were impelled by their enthusiasm to labour for its advancement; and this, said the speaker, was an early proof of the fact that as a general rule the university was the centre of research as well as of teaching. Those who are keen enough to make good teachers are sure to be investigators. The same principle is to be seen to-day in the universities of America, where success is measured by the number of students who remain to continue their studies after graduation. Knowledge gained under such a system is living and not dead; too great an insistence on the examination system was apt to lead to a mere aggregation of dead knowledge. The speaker next attended to the matter of public control. Even in the University of Paris public control was provided for by giving the Chancellor, an ecclesiastical authority, the right to license teachers, a right exercised in conjunction with the University itself. This outside authority has been constitutionalised in modern universities, such as Bristol. The Chancellor's supreme power acts through the medium of court and council. Alluding to the matter of degrees, Sir Isambard Owen inveighed against the notion that the granting of degrees was the sole end and aim of a University, remarking that in Germany only a minority of students proceed to degrees, a remark the significance of which was appreciated by the audience with applause. On the other hand, the type of education which fits a student to become a wageearner was a necessary part of the university and must not be despised. "I cannot close my address," said the speaker, "without saying something about the democratic character of all mediæval universities." In such class distinctions were absolutely non-existent, owing to the predominance of the ecclesiastical over the feudal influence. The church sought for the best brains and sought for them in all classes. He saw with delight that the corporation of Bristol had devoted a large share of its university contributions to such ends by means of scholarships. Among all the types of fight which formed the sport of the mediæval universities he had never read of one between rich and poor. "All seemed to recognise the solidarity of their interests and the common brotherhood of the students."

UNIVERSITY COLLEGE HOSPITAL MEDICAL SCHOOL.
INTRODUCTORY ADDRESS BY SIR JOHN TWEEDY, LL.D.,
F.R.C.S. ENG., EMERITUS PROFESSOR OF OPHTHALMIC
MEDICINE AND SURGERY IN UNIVERSITY COLLEGE,
LONDON.

AFTER a sympathetic reference to the loss sustained by the school in the recent death of Dr. H. Radoliffe Crocker, Sir JOHN TWEEDY congratulated the prize-winners, reminding them that character as well as cleverness, and wisdom as well as knowledge, were necessary elements of success. The modern medical curriculum was such that conspicuous inaptitude for practical art was scarcely possible to the qualified practitioner. This was not always the case, as was instanced by Arnald of Villanova, one of the chief medical luminaries of the thirteenth century, who related that he knew an excellent professor of natural science learned in medical theory who could not treat the simplest ailment. This was an extreme type which was now extinct. As the antithesis of the learned but inexpert man there was in all professions the so-called "practical man," whose merits were generally overrated in popular estimation and whose lack of theoretical knowledge was often imputed to him for righteousness. Nor could it be denied that not infrequently he did attain a certain level of success, but he had narrow limitations. He dealt in particulars, was often quick to observe similarities, and in the treatment of disease concerned himself with symptoms without troubling to investigate the physical conditions upon which those symptoms might depend. Science arose from the discovery of identity or unity amid diversity of manifestation, and it was precisely here that the practical man so often failed. He appreciated agreements and similarities, but failed to discriminate differences. Such men were not altogether without illumination. Sir

John Tweedy proceeded to welcome the newcomers to the study of medicine and to congratulate them on their choice of a career. He maintained that there was no secular calling so philanthropic in its aim, so refining in its influence, and so beneficent in its operation as the practice of medicine. Like mercy, it was twice blessed: it blessed both patient and practitioner. Medicine was only worthily served when it was practised as a cult, in the devout spirit of worship. It must be served loyally and for itself. Sir John Tweedy continued: "Those who are now beginning medical study may, at the outset, be perplexed and discouraged by the new method of study and by the new order of ideas to which they are introduced. Heretofore the education of the student has been chiefly literary, based upon pedagogic authority and the dictatorship of books. Henceforth both the character and method of study will be altered. The influence of authority will still obtain; much knowledge must be taken on trust, but it is a critical trust. Whatever is taught here is based upon a knowledge which may have been the accumulation of centuries, or it may be knowledge recently acquired, but it is knowledge which in due time and place is capable of verification and demonstration. While this knowledge is based upon authority, it is the authority of persons who have examined it with care and attention and who have been competent to form a sound opinion upon it. In later life most of us, as Cornewall Denis upon it. In later life most of its, as consequently that remarked in his Essay on Authority, must accept much of our knowledge on the trust of our own authority. We have gone through a process of thought and investigation and have arrived at a given conclusion, but the reasons of that conclusion have passed out of memory. We hold these opinions rather upon the recollection of having once ascertained them to be well-grounded than from a clear present perception of these grounds. If this were not so we should, as Locke observes, be perpetually floating about in doubt and be at the mercy of those who have a readier or more retentive memory, or who have happened to master the arguments on one side of the question only. The growth of medical knowledge has been slow and subject to cyclical variations, sometimes to retrogression, sometimes almost to eclipse. But it has grown, 'creeping on from point to point.' The history of medicine furnishes many illustrations of this. In human anatomy, for example, it would at first sight seem to be easy, with due diligence, to ascertain and correctly describe the structure of the human frame, but it took many centuries of practical observation to reach even an approximate degree of accuracy. Aristotle, Hippocrates, Praxagorus, and other physicians of the Hellenic and the Alexandrian schools, studied anatomy, and yet the records of their observations contain many errors both of observation and of reasoning. Even Galen, who was considered the infallible oracle for fourteen centuries and who was the first to seriously study the science of anatomy and made many discoveries therein, also promulgated many errors. notwithstanding the impulse which Thaddeus and Mundinus gave to the study of anatomy at the school of Bologna in the thirteenth century the authority of Galen was so firmly established that when Vesalius in the middle of the sixteenth century published his famous work on Human Anatomy in which he corrected many of Galen's errors, there were not wanting anatomists who impeached the accuracy of Vesalius, or when this was no longer possible affirmed that the human organisation had undergone structural change since Galen's time. Now there is not a first year's student who will not be able daily to verify every statement made by his teacher or contained in his textbook. The progress of physiology has been even slower than that of anatomy. Indeed, scientific physiology is almost entirely the work of our own time. 40 years ago physiology was taught in University College by the greatest exponent of the day, I mean the illustrious Sharpey, but the physiology which he taught was almost entirely didactic and expository. There was practically no experimentation and scarcely any attempt at practical demonstration. Now physiology is eminently experimental, and the splendid position which it has attained amongst the natural sciences is the result of the employment of the experimental method. The course of medical education is progressive in complexity. In the earlier studies the method is authoritative and demonstrative, but in the final studies of medicine and surgery the method is more conjectural and

ratiocinative. Here exact observation, well-trained senses, and correct reasoning are the critical apparatus required. The problems to be solved are more complex and more obscure than those of anatomy and physiology. The difficulties of investigation are greater; the phenomena to be observed more difficult of interpretation, and the means of verification are fewer. In clinical medicine it is rarely possible to conduct an exact experimental inquiry, for we can seldom isolate the phenomenon under observation by an artificial arrangement of circumstances. As Mill has pointed out, there is this essential difference between Observation and Experiment: in observation we find our instance in Nature; in experiment we make it by an artificial arrangement of circumstances. Hence the growth of medical knowledge has been slow and halting. Centuries of observation by experienced workers have been needed to raise practical medicine to its present high level. But these observations have for the most part only improved the art of medicine and have done comparatively little for the advancement of its science. The science of medicine has been advanced mainly by the researches of those who have not been directly engaged in the treatment of disease. When new knowledge has been discovered by these means it has been received by competent judges, and by the influence of their authority it has been accredited and diffused. Failure to appreciate the difference between the dissemination of knowledge and the advance of knowledge has given rise to much confusion of thought and not a little waste of endeavour. Perhaps the crudest manifestation of this confusion is the belief, real or feigned, by some persons that inquisitorial experiments are performed in hospitals on men, or on animals, or both. Less crude—nay, even creditable in a sense—is the notion that by establishing sanatoria or endowing special hospitals for the treatment of particular classes of general diseases, it is possible to solve the problem of the nature and origin of these diseases and to hasten the discovery of the means of prevention and cure. Logically, this assumption is false; economically, it is wasteful. The great desideratum of our day is adequate endowment of biological and pathological research as the surest and most humane way of discovering the nature and cause of disease and the means of its prevention. Clinical observation only deals with disease when and as it manifests itself in man and animals; it throws but little light upon the causes of disease or upon the intimate processes which constitute the pathological state. Supremely useful as hospitals are for the purpose of treating the sick by the help of the best skill and knowledge of the time, and as schools for the training of successive generations of medical practitioners for the service of the community, it is nevertheless true that most of the capital discoveries of scientific medicine have been made outside hospitals and very often apart from clinical observation altogether. Among the most remarkable of these discoveries I may mention those relating to malaria, Malta fever, yellow fever, and I might add other diseases, which have baffled the best clinicians for centuries. In surgery, too, it may be said that the scientific basis of the modern aseptic method has been established not by clinical observation but by experimental research.'

Sir John Tweedy proceeded to illustrate this thesis by recounting the history of the use of the ligature for wounded arteries, and in this connexion he made an interesting quotation from the Apologia of Dr. J. F. D. Jones defending the experiments which he had made upon horses, and which resulted in the adoption of the modern method. The future practitioners of medicine would have to form an opinion on the justifiability of experiments upon living animals for the purposes of scientific research, and if they were satisfied that these experiments were justifiable with proper safe-guards they would be called upon to defend the practice and to justify their opinion. To do this intelligently it was necessary not only that they should be acquainted with the arguments for the defence but that they should also make themselves masters of the arguments on the other side. It was not enough to ascribe the opposition of the public to ignorance or fanaticism. There might be either or both, but objection could be only overcome and acquiescence gained by enlightening and educating the public mind. It should be remembered that the mass of a nation must be convinced of the value of a general principle which is being carried out, else nexion Dr. Goodall said "that if all teachers of physiology what we might judge the most salutary change would be in London hospitals would constantly bear in mind that they ineffectual. Ritchie, in discussing the Rights of Minorities, are teaching physiology to men who are going to be doctors,

had remarked that on matters of public health only the scientific expert could, in the first instance, form a sound judgment. In democratic societies there was often a distrust of scientific opinion. The remedy was not despotism but public enlightenment, and the scientific specialist was bound therefore by patriotism, as well as in the interests of his own science, to lend what aid he could to the popularisation of science from which he was too apt to recoil. It was the sole antidote to ignorance or pseudo-science. Those whom science neglected, fanaticism and quackery would claim for their own.

MIDDLESEX HOSPITAL.

INTRODUCTORY ADDRESS ON "WALKING THE HOSPITAL," DELIVERED BY J. STRICKLAND GOODALL, M.B. LOND., LECTURER ON PHYSIOLOGY AT, AND SUB-DEAN OF, THE HOSPITAL

AFTER remarking that an opening address at least had an educational value for its giver, and welcoming Lieutenant Shackleton as the prize-giver, Dr. Goodall welcomed the new students in terms of congratulation on their choice of the most interesting and least monotonous occupation in the world for their means of livelihood, and gave some excellent advice concerning the best means of preparation for its pursuit. After congratulating Sir Henry Morris and Professor Arthur Robinson on the distinctions conferred upon them during the past year, he opened his remarks on "Walking the Hospital" in the following words:—

"Doctors, like poets, are, I believe, born, not made, but it is perhaps just as well for the general public that, unlike the latter, they have to undergo a definite course of study which is usually known by the laity as 'walking the hospital,' a mysterious and lengthy performance which (also according to the laity) lasts a varying number of years, usually costs the parents an indefinite amount of money, and is *supposed* to be associated with much experimentation on the hapless poor. This afternoon I propose to give you a brief general outline of what 'walking the hospital' really is. At the present time under favourable conditions the process of walking the hospital takes about five years, this being the minimum time allowed by law. It has, I believe, been known to take longer, the long distance (time) record at present being, I understand, held by a gentleman who has up to now devoted 22 years of his life to it without either tiring of the amusement, ruining his health from over-study or satisfying the examiners. In the case of the London University medical curriculum five and a half years is the minimum time allowed, the extra half year having recently been added, possibly to enable the teachers and the students to master the regulations.

Dr. Goodall proceeded to describe the different stages of the medical curriculum, dwelling on the importance of each of its subjects to the education of the medical practitioner. After discussing shortly the preliminary sciences he spoke of anatomy, of which he said: "The importance of a knowledge of this science is readily appreciated by the student, for he at once sees the obvious impossibility, without it, of performing (with any degree of safety to the patient) any surgical operation or of conducting satisfactorily any medical or surgical examination. In fact, I once heard surgery defined (I must admit by an anatomist) as anatomy plus common sense.

Passing on to consider physiology, Dr. Goodall described that science as the key to anatomy, and the basis of pathology and of rational treatment in medicine. He regretted that it was, as he believed, less popular with the average student than anatomy, a fact which he attributed to two causes. Firstly, because in anatomy all the practical work is carried out by the student himself on the human body, and he consequently realises from the first that he is learning something which will be of immediate use to him in his professional work; while in physiology so many of the observations are of necessity carried out on the lower animals, and so much of the subject is theoretical or very difficult of demonstration, that the student is apt to overlook the direct practical bearing of such experiments on man. Secondly, because in the London schools, at any rate, anatomy was, as a rule, so much better taught than physiology. In this connexion Dr. Goodall said "that if all teachers of physiology in London hospitals would constantly bear in mind that they

not physiologists, and if they had the strength of mind to eschew those more purely academic parts of the subject which have no practical bearing on medicine, and finally if they had sufficient moral courage and self-denial to abandon for ever Pflüger's law, electrotonus, and the veratrine curve, and to substitute for them classes of applied human physiology in which the student was properly taught the systematic application of physiological methods for the investigation of the functions of the different organs and systems in the human body, then we should, I believe, have physiology occupying its proper position in the systematic practice of medicine and of treatment and enjoying a popularity with the student and practitioner which it never has enjoyed, and never will enjoy, under existing conditions. For what could be less useful to the average medical man than a knowledge of the veratrine curve or Pflüger's law, or what more useful than a really practical knowledge of the physiology of the normal human pulse. Yet I do not hesitate to say that the former have been asked twenty times in practical physiological examinations to the The great danger of specialisation in any latter's once. subject is, I take it, loss of judgment and perspective in relation to other subjects, and there has perhaps in the past been rather too much specialisation in anatomy and physiology. An up-to-date knowledge of surgery is, I venture to think, essential for the teacher of anatomy, as also is an up-to-date knowledge of medicine to the teacher of physiology in medical schools if they are to retain their perspective and judgment and teach use/ul anatomy or useful physiology to medical students. And here, lest some of you might be led to think that physiology has done little for medical progress, I would remind you of some of the more direct contributions of the physiologist to practical medicine. Adrenalin, a valuable natural hæmostatic now in daily universal use, is essentially the outcome of physiological research. The treatment of myxœdema and cretinism by thyroid extract, the nerve paths in the central nervous system, the influence of gravity on the circulation, the safe limits of chloroform anæsthesia, the nature of caisson disease, mountain and balloon sickness, are all direct offerings of the physiologist to the physician; and I would mention Pawlow's epochmarking work on digestion, for I doubt if there is any book written on medical treatment proper which is so pregnant in suggestion of rational treatment as is this, which is usually regarded as an almost purely physiological work. Researchers in physiology owe no debt to practical medicine, but teachers of physiology in medical schools do owe a great debt to practitioners of medicine."

Dr. Goodall then described the many studies and activities comprised in the clinical portion of the medical curriculum. He dwelt upon the importance of a working knowledge of physiology for their proper pursuit, and also of a study of the individual temperaments and peculiarities of different persons placed under similar conditions. "The importance of a psychic factor," he said, "is well recognised in ordinary physiological processes; for instance, with a psychic stimulus (appetite) one can digest four times as much food in a given time as without it. While as regards disease, I believe I am not wrong in saying that the psychic factor is, from the patient's point of view, the worst in every case. The truth of this remark is, I think, quite obvious in the case of such gross diseases as, say, cancer or leprosy, where the knowledge that the condition is more or less incurable and often loathsome to others is, I am sure, nine times out of ten, far more soul-racking to the patient and cause him (or her) far more suffering than the actual disease itself. While even in such a comparatively simple condition as a broken leg, more often than not, the mental state induced by the enforced rest and absence from business is a cause of far greater suffering to the patient than the actual pain or discomfort caused by the wound or injury. If this is correct, surely it is a factor which must be recognised and treated just as much as the actual pathological condition. The danger of this belief lies in the fact that one may exaggerate its importance and so over-treat it to the neglect of the actual physical factor. Ignore the psychic factor and your treatment may, in the case of a sensitive patient, amount to actual brutality, for I would here remind you that no pain is so easy to provoke as mental pain and none so difficult to alleviate. Over-treat the psychic factor on the other hand and you yourself become a quack and run the risk of making your patient a chronic neurasthenic!"

Dr. Goodall proceeded to point out the advantages of watching the methods and manners of some of the most successful and eminent men in the medical profession enjoyed by students during their hospital education, and showed the enormous importance of fulfilling thoroughly the various clinical offices in the wards and out-patient departments. He described the advantages of the social side of the student's life, said a word on behalf of the Officers' Training Corps, and concluded with these words: "Finally, gentlemen, it is during your hospital career that you will make friendships that will in many cases endure as long as you endure. Real friendships, I believe, are only made while young, and can only exist between persons of like tastes and ambitions, and it is here during your life in the hospital that you will be brought in contact with men of like age and similar tastes and ambitions to your own, for I think it is Sallust who says 'idem velle atque idem nolle, ea demum firma amicitia est,' which perhaps I might be allowed to translate for you as 'to have the same desires, the same aversions, that, and that alone is stable friendship!' In conclusion, if I might offer one line of advice it would be-Don't make friends of your patients or patients of your friends.'

A Lecture

ON

THE CLINICAL SIGNIFICANCE OF ALBUMINURIA.

Delivered at King's College Hospital

By NESTOR TIRARD, M.D. Lond., F.R.C.P. Lond.,

SENIOR PHYSICIAN TO KING'S COLLEGE HOSPITAL; PROFESSOR OF MEDICINE, KING'S COLLEGE.

GENTLEMEN, -The chief difficulty connected with cases of albuminuria is not concerned with the detection of minute traces, but with the determination of the significance of the albuminuria in the individual case. It is a somewhatcurious feature that in endeavouring to elucidate this question the amount of albumin that has been revealed by chemical processes is often a relatively minor consideration. Frequently when relatively large quantities are present a favourable opinion may ultimately be expressed, and conversely when only small traces are found and when at times the urine may give no decided reaction an unfavourable prognosis may be inevitable. The examiner for life assurance is, no doubt, right in deferring or refusing to accept at ordinary rates those individuals whose urine gives a reaction for albumin at the first examination, but this single observation will not justify rejection unless the presence of albumin is accompanied by numerous other indications of graveorganic lesion. It is well known that the course generally adopted by medical officers of experience entails a second visit and a reference to the medical attendant of the proposed. The medical attendant is obviously more likely to be able to conduct the series of observations which may furnish data for a diagnosis, and he may already be in possession of information which has not been disclosed to the examiner of the assurance company.

These considerations, derived from actual practice of an important branch of medical work, suffice to support the comparatively small amount of information afforded by the mere presence of albumin in the urine. It is a signal of possible danger, it is a call for caution, it may the first indication to point to the necessity of radical changes in the habits and occupation of the individual directly concerned, but it cannot alone warrant anything more than a bare statement of fact. It is only a starting point, comparable to a single observation of the temperature of the body or of the rapidity of the pulse; the significance must be sought from the consideration of numerous other factors, some connected with the extent and the frequency of the albuminuria, others with the general condition of the urine, such as the amount passed in 24 hours, the specific gravity and the colour, or the presence of other abnormal constituents, but in very many cases these data will be found to be supported or negatived by others relating to the

previous history, and by numerous factors obtained from a careful and detailed examination of other physiological **sys**tems.

One of the first elements to be considered is necessarily the occasion which has led to the examination of the urine and the detection of the albumin. When the condition has been ascertained in an individual who is applying for a life assurance policy, or for a certificate relating to his physical fitness to undertake some appointment, there will probably be no complaint of any symptom of weakness, and there may possibly be very little in the history to throw any light upon the cause of the albuminuria. The albumin may, indeed, come as a surprise at the end of an examination which has been otherwise satisfactory. These cases stand in an entirely separate category from that to which those patients belong who have some definite complaint for which they require the advice of a medical man, and accordingly come with perhaps a somewhat vague, or even misleading, account of symptoms. These, again, can be grouped apart from those in whom albuminuria is to be anticipated as a necessary consequence of the disease from which they are suffering.

These three groups of cases do not strictly conform to any definite classification of the causes or of the importance of albuminuria, but it may be well to bear them in mind as they must influence the spirit in which the question of elucidation is approached. Thus, for example, the type of symptomatic albuminuria so often met in various febrile conditions does not cause any immediate anxiety; it is noted as one of the many indications of the severity of the febrile state, and to this extent it has a certain importance. Febrile albuminuria, however, appears never to be associated with any grave interference with the actual work of the kidney, it is not an indication of the need of any special modification of treatment, and it is extremely doubtful whether it ever forms the starting point of chronic renal changes which will give trouble at a later period.

To illustrate this statement by a definite example, I may remind you of the frequency with which albumin is detected in the course of acute lobar pneumonia during the precritical stage; in this the symptom is an evidence of toxemia, but the degree of toxemia can be gauged by numerous other indications apart from an examination of the urine. Other symptoms are present from which the same inference can be deduced with comparative certainty; anxiety may be aroused by the condition of the pulse, by sleeplessness or delirium, by the rapidity of respiration, or by the degree of fever, without any reference to the albuminuria. If the patient passes the crisis safely the albumin speedily disappears, and it does not return.

Another example of symptomatic albuminuria is often shown in patients who are suffering from any disease involving retardation of the blood-flow in the renal capillaries, as with failure of compensation with heart disease, or with many chronic pulmonary conditions. Numerous patients with this symptomatic form of albuminuria have been under observation in the wards during the past few months, but in these cases, as in the febrile group, the albumin rarely causes When the sequence of events is not clear, when there may be reason to suspect that the albumin has preceded the cardiac changes, the prognosis will be affected, but when there is little doubt that it is the consequence rather than the cause, the albuminuria is not considered to merit very much attention. After a spell of cold and foggy weather there are always several patients in my wards with severe bronchitis, associated with definite evidence of bronchial spasm, and in the majority of these patients albumin is found in the urine during the period of greatest pulmonary distress. As in pneumonia, no symptoms can be assigned to this change in the urine, and the treatment is entirely guided by the pulmonary condition. As this improves the albumin disappears, this change affording proof, if any were needed, of the purely symptomatic nature of the albuminuria. In some of these patients there has been a certain degree of dropsy of the lower limbs, but this has been associated with so much cyanosis that it has not served to obscure the diagnosis or to lead to modification of the treatment.

The detection of albumin in connexion with evidence of heart lesions often opens up a more difficult problem; it is not always easy to express an opinion as to the significance of the albumin without more evidence than is probably available from the notes of the present condition. The they will therefore merely be a further indication of albumin,

amount of urine passed in 24 hours, the specific gravity, the amount of albumin present on successive days, and numerous factors connected with the general condition of the patient will have to be considered before it is safe to hazard a provisional diagnosis. To enter into details upon these points would carry me far beyond the limits of the present lecture, so I must content myself with briefly reminding you of the frequency with which your attention has been directed to the information to be gained from the aspect of the patient, the presence or absence of the subconjunctival tear, the extent of the cedema, and the character of the pulse. Before leaving the consideration of these cases of albuminuria accompanying heart murmurs it is necessary to remind you that great care must be exercised in connexion with the position of the cardiac impulse; in many forms of heart disease the cardiac impulse is displaced outwards, and since a similar condition occurs with chronic forms of renal disease you must be on your guard against drawing an erroneous inference from this indication.

Symptomatic albuminuria is so often seen in our wards that it does not appear necessary for me to deal with it at greater length. Ward work, however, and even an extensive experience of the out-patient department, will scarcely prepare you for many of the difficulties to be encountered in after life, and it is on this account that I think it is desirable to furnish you with a few hints which may be helpful after you have left the hospital. Albuminuria has been aptly termed a silent symptom; it may be detected when there has been no marked evidence of trouble to attract attention, and let me remind you again that although it does not necessarily indicate a serious organic lesion, the presence of albumin should always call for careful and repeated observation.

An initial error against which I would warn you is the attempt to measure the importance of the albuminuria by the amount detected at any time; albuminuria can never be a negligible quantity; it always has a definite significance, but it is far from correct to attempt to estimate the importance in direct terms of the amount of albumin. It is quite true that when a large amount is being lost daily the nutrition of the individual will necessarily suffer, but it is not safe to infer that because only a small amount is occasionally detected therefore it is of relatively small importance. Some of the most serious forms of albuminuria are those in which the detection of albumin may at times be a matter of difficulty, and in this they agree with many of the milder forms of functional, cyclic, or orthostatic albuminuria. In practical work, therefore, it is essential that you should be prepared to differentiate these cases, and this can generally be effected with comparative ease if attention is not limited too exclusively to the condition of the urine. There are, of course, certain features of the urine which must be noted, and foremost amongst these is the specific gravity. Before attaching much importance to the specific gravity, it is necessary to know numerous factors connected with the specimen—e.g., the relation of the time it was passed to the ingestion of liquids, the permanent nature of a relatively high or low specific gravity, and the possibility of some disturbing factor, such as an attack of diarrhea, recent violent exercise with consequent profuse perspiration, or even an excessive degree of nervousness at the mere fact of examination. To each and all of these disturbing influences due consideration must be paid, and from this brief summary you will readily infer that in insurance work, at least, where the proposer is seen under conditions which preclude a full knowledge of many of them, very little importance can be attached to an indication which, under other circumstances, is of supreme value.

The colour of the urine is to such a large extent dependent upon the degree of dilution, with which, of course, the specific gravity will also vary, that it is similarly also of very little assistance, though if we know that the urine is generally of a pale colour and the specific gravity is usually low, these facts will go far towards enabling a diagnosis to be made in a case in which a small amount of albumin has been found.

The presence of casts may be of material assistance, provided that too much importance is not attached to a few hyaline casts. Since the introduction of the custom of examining centrifugalised samples of urine which has been recently voided, there can be no doubt that hyaline casts are more frequently found. It must be remembered that such casts are likely to be present whenever albumin is found in acid urine,

without affording much more than negative evidence. They may be present in any of the types of albuminuria which are not associated with definite structural renal changes. They may be present in the orthostatic forms of albuminuria, and they may also be found in connexion with some cardiac cases, though in the latter class they may be accompanied by blood casts or by free blood corpuscles. On the other hand, other forms of casts if present may afford very valuable information of true organic renal changes, especially of chronic tubal nephritis. To a far more limited degree they may also favour a diagnosis of chronic interstitial nephritis, since it must be remembered that in this condition both casts and albumin may occasionally be absent for long periods. With regard to casts, therefore, the utmost that can be said is that their presence may be very suggestive, but that it will generally be unsafe to lay much stress upon their absence as a proof of the non-existence of possibly serious structural renal changes.

In the course of the routine examination of the individual it is probable that alteration of the cardiac sounds and of the position of the cardiac impulse will already have been noted, but it is quite possible that prior to the detection of albumin they may have been assigned to some less serious When dealing with those who have been long addicted to athletic exercises it is by no means uncommon to find some degree of cardiac hypertrophy and some accentuation of the force of the ventricular systole. These changes I have often found in rowing men, in those who have done long distance races, and in those who have exerted themselves with excessive cycle-riding, either in forcing the pace, in riding over-weighted machines, or in recklessly endeavouring to cope with hills. It must be remembered that such errors of judgment are most frequently, though not exclusively, limited to the period of adolescence, and that this is a time in which many types of albuminuria are likely to be detected. Incidentally, I would remind you that these conditions of overstrain may alone account for temporary albuminuria; this has been proved amongst rowing men at the Universities, and there appears very little room for doubt that it is true for all forms of violent muscular overstrain. The practical outcome, then, is that before attempting mentally to connect the cardiac changes with the albuminuria we must endeavour to determine whether they may not both be due to a common cause. Although this holds good when it is a young man who is being examined, the same degree of charity can rarely be conceded to a man of middle age in whom similar changes of the position of the cardiac impulse, and similar booming systolic sounds have been found at the apex. In this case it is highly probable that in addition to these changes there will be well-marked alterations in the sounds audible over the aortic area. The second sound is commonly sharp, clear, and ringing in character, and it is also probable that the diastolic sound may be reduplicated. This separation of the diastolic sound into its two constituents indicates an appreciable difference in the time of the closure of the aortic and the pulmonary valves respectively, which in turn is an evidence of an alteration in the normal relationship of the capacity of the two ventricles and also of the normal relation of the blood pressure in the aorta and the pulmonary artery.

In all probability before the examination of the urine the character of the pulse will also have received attention, and will perhaps have furnished some indications of value. A rapid pulse may rightly have been ascribed to nervousness under the ordeal of an examination upon which much may depend; comparatively little importance is generally attached to a mere increase in rate. More importance belongs to irregularity of rhythm, since although this may commonly be present with mitral lesions it is also frequently to be met with in chronic forms of albuminuria dependent upon structural lesions of renal tissue. There is no sequential association between functional or orthostatic albuminuria and an irregular or intermittent pulse. The two conditions may be found in the same patient, but some cause other than albuminuria must be sought to explain the abnormality of

In the separation of functional from organic forms of albuminuria indications of rigidity of the wall of the artery are not of material help, inasmuch as they do not occur until comparatively late in life when there is little ground for until comparatively late in life when there is little ground for suspecting a functional type of albuminuria. On the other is not a disease. Therefore, as with every other symptom,

hand, evidence of arteriosclerosis is extremely significant. and this may be estimated directly by the sense of resistance, by the sphygmomanometer, or by the sphygmograph. The first method is still largely used, though it requires considerable experience before it can be trusted to give much more than a rough indication, and there is always a fear of the introduction of the personal equation. The different forms of sphygmomanometer aim at replacing this personal factor by greater scientific accuracy, and in many cases the claim is fully justified. My experience has, however, led me to be somewhat cautious in accepting the results with implicit confidence; although usually trustworthy, the evidence afforded by the sphygmomanometer is from time to time distinctly at variance with the physical signs. In my hands the sphygmograph has given greater satisfaction as an evidence of high blood pressure, and therefore it has frequently been of material assistance in differentiating functional from organic types of albuminuria.

Comparatively recently the suggestion was made that the differentiation could be effected with ease by the administration of calcium lactate. This suggestion was based upon certain investigations which appeared conclusive, but in actual clinical work, both in hospital and in private, this simple method has not, so far as I have seen, equalled the expectations it aroused. It has been endorsed by some observers, but those who have found it successful are, I believe, far outnumbered by those who have been disappointed. Whether further experience will lead me to modify this opinion I cannot say, but I am convinced at present that it would be unwise to neglect the evidence afforded by the other observations, and to trust implicitly to a therapeutic experiment for the diagnosis.

Hitherto stress has been laid upon the different modes of conducting the examination when albumin has been unexpectedly discovered, but it must be remembered that often valuable indications are to be recognised before any systematic examination has been made. Thus due regard must be paid to the age of the person and to his appearance. Almost instinctively you will learn to recognise the pallor and the watery look of the eye of an individual who is suffering from chronic tubal nephritis, even when there is little or no cedema discoverable in any of the usual sites. Frequently also the aspect of the man with chronic interstitial nephritis is suggestive of antecedent gouty condition, or of chronic dyspeptic troubles, or in earlier stages in younger men the face may betray signs of a life that has been full of financial or other anxieties. Conversely, while many young men are devoid of any facial indication of orthostatic, cyclic, or functional albuminuria, you will not infrequently note an almost indefinable change of aspect which you will learn to associate with these conditions.

To summarise the conclusions, a large amount of albumin, without blood or pus, may generally be taken to indicate chronic tubal nephritis, and this can be confirmed by a high specific gravity, by microscopic examination, and by the appearance of the patient. A very small trace in an elderly or middle-aged man will probably indicate chronic interstitial nephritis; confirmatory evidence can be found in the aspect, the history, the pulse tension and tracing, the outward displacement of the cardiac impulse, the accentuation of the systolic apical sound, and the accentuation and reduplication of the second sound at the base of the heart. These indications may be further supported in some cases by the pale colour and low specific gravity of the urine; less frequently information may be gathered from the presence of casts and from their predominant characteristics. absence of casts is not, however, to be regarded as an indication that the case is not one of chronic interstitial nephritis. In a young man a mere trace of albumin may be the only evidence of a functional albuminuria, and the diagnosis must then rest upon negative evidence to a large extent, one of the most important factors being the relatively high specific gravity, unless this has been influenced by nervousness or by the recent consumption of a large quantity of liquid. the same limitations the deep colour of the urine will lend confirmatory evidence.

There are so many causes for great variations in the condition of the urine that stress cannot be laid upon the amount of albumin without paying due regard to most of the changes which have been touched upon in this lecture. After all, by itself it affords no reasonable ground for a diagnosis Numerous other signs and symptoms must be carefully weighed, perhaps at short intervals, before it is justifiable to express more than a provisional diagnosis.

AN INVESTIGATION INTO THE ETIOLOGY OF ERYSIPELAS AND ALLIED INFECTIONS.

BY P. N. PANTON, M.A., M.B., B.C. CANTAB., CLINICAL PATHOLOGIST TO THE LONDON HOSPITAL; AND

J. E. ADAMS, M.B., B.S. LOND., F.R.C.S. ENG., LATE SURGICAL REGISTRAR AND RESIDENT ASSISTANT SURGEON TO ST. THOMAS'S HOSPITAL,

THE present investigation was undertaken with a view to determining certain disputed points in the etiology of erysipelas and the allied inflammatory lesions, cellulitis and lymphangitis. Erysipelas is commonly defined as a "specific and contagious infective disease due to the development of the streptococcus erysipelatis of Fehleisen in the smaller lymphatics of the skin." It has for long been a matter of dispute as to whether or not the streptococcus erysipelatis should rank as a specific organism, and it appears now to be generally taught that this streptococcus progenes, but in order to account for certain discrepancies it is described as "of a certain degree of virulence," 2 yet the term streptococcus erysipelatis is still retained in the majority of descriptions of the disease. In addition to erysipelas proper a more extensive type of acute superficial inflammation is defined under the titles of "phlegmonous" and "cellulo-cutaneous erysipelas." In this variety certain clinical features are described by which it may be distinguished from erysipelas on the one hand and cellulitis on the other; it is stated to be doubtful whether or not it is contagious, and it has been suggested to be the product of a mixed streptococcal infection, "the erysipelas organism growing in the skin and the streptococcus pyogenes in the deeper structures." 4 Two further conditions of acute superficial spreading inflammation with which erysipelas is liable to be confounded are those of cellulitis and of acute lymphangitis in its later stages. While the specific nature of erysipelas is widely recognised, it is allowed that a spreading inflammation of the subcutaneous tissues-or cellulitis-which presents distinctive clinical features, may be produced by a variety of organisms, and that in some of the more localised forms the staphylococcus pyogenes aureus is the causative agent. Acute lymphangitis, in the same way, has no claim to be considered as a specific disease and neither this condition nor that of cellulitis is anywhere liable to "notification."

In considering the etiology of erysipelas it is necessary to determine the nature of the organism which causes the condition, and the relation which it bears, if any, to the organisms present in such allied inflammations as cellulitis and lymphangitis. Of recent years a considerable amount of work has been done upon the differentiation of the streptococci and their classification. Andrewes and Horder 6 have isolated a large number of streptococci from various sources and have been able to arrange them into a few fairly definite groups which depend for their differentiation mainly upon the reactions set up by the organisms in the carbohydrate media introduced by Gordon. The streptococci are thus found to fall into three main groups, representing three fairly constant varieties, which have been classed by Andrewes and Horder under the names of the strepto-coccus pyogenes, the streptococcus fæcalis, and the streptococcus salivarius, with its closely allied variant the streptococcus anginosus. In the same manner the pneumococci, while presenting many points of similarity with the streptococci, are found to form a distinctive group, possessing fairly constant reactions. In this investigation an attempt has been made to isolate the causative organism from cases of erysipelas, and of the similar acute spreading inflammations of the skin and subcutaneous tissues, and to subject them to all possible cultural tests, including Gordon's carbohydrate media, with the object of determining whether the causative organism of erysipelas is a constant one, and whether it presents any features by which it may be distinguished from the other pyogenic streptococci.

These questions are of some practical importance since the various surgical procedures which have been adopted in cases of erysipelas appear to have no recognisable influence in shortening the course of the disease and of recent years treatment by serum-therapy has been largely employed. The serum used has been derived from various sources. The so-called anti-erysipelas serum is usually derived from the serum of a horse which has been inoculated with a mixed culture of streptococci obtained from several cases of erysipelas; sometimes a streptococcus pyogenes serum is used, the horse in this case having been immunised by a pure culture of one or more strains of the streptococcus pyogenes; a "polyvalent" streptococcal serum is also employed and is obtained from various strains of streptococci chosen indiscriminately from different lesions. Uncertain as is the value of serum-therapy in erysipelas, it would obviously be of importance to ascertain if all cases of erysipelas are due to the same organism before drawing any conclusions as to the value of serum treatment in any particular series of cases.

In addition to the bacteriology of these infections certain points in their histology have been investigated when the necessary material has been available. The various cases were taken from the wards and out-patient department of St. Thomas's Hospital, and in each instance the source and mode of infection were investigated so far as it was possible. A review of all cases of erysipelas admitted to, or arising in, the hospital over a period of 12 years was also made in order to determine if cases of erysipelas, by spread of infection, gave rise to this disease only, and, conversely, if other septic conditions ever gave rise to erysipelas. The answer to these questions, upon which the specific character of erysipelas depends, determines the manner of dealing with these cases. Should erysipelas patients alone be isolated, or should all cases of streptococcus infections be placed

Technique.—In the erysipelas cases films were made and cultures taken from the exudation of the wound when this was available. The films were stained by Gram's method and the culture media employed were "lemco" broth and nasgar. In cases of mixed infection an isolated streptococcus colony was, when possible, inoculated on to a second nasgar tube and the subsequent growth transferred to the various media; isolation by plating on Petri dishes was usually avoided, since the colonies thus obtained frequently died out on being transferred to liquid media. The behaviour of the streptococci thus obtained upon agar and gelatin, in litmus milk, broth, neutral red broth under anaerobic conditions, and a large number of Gordon's carbohydrate media, was in each case fully investigated. In a certain number of instances, however, owing to the presence of other actively growing organisms, the nature of the streptococcus present could not be determined. In a number of cases in which blebs of considerable size were present, these were opened aseptically and several loopfuls of their contents smeared over a nasgar slope. In a few cases in which neither a discharging wound nor blebs were present the skin at the spreading edge of the rash was scarified with a sterile needle and cultures taken from the exuding serum. In some instances films made from the bleb contents or from the clear serum obtained on scarifying the skin were treated by Leishman's stain and a differential count was made of the cells present. In only one or two cases could portions of the skin be obtained for histological purposes. In the cellulitis and lymphangitis cases films and cultures were investigated in a similar way, and were obtained either from the original wound or from the pus evacuated at the time of operation. In several of the cellulitis cases small portions of the skin were removed during the operation for microscopy. In all about 60 cases were investigated, the majority of which were diagnosed as erysipelas; a few cases in which an operation was followed by a spreading erythema of doubtful nature are also included.

The crysipelas infections.—Out of 60 cases examined bacteriologically 38 were considered on clinical grounds to be typical instances of erysipelas. The following is a short

account of a few of such cases as illustrate points of importance in the etiology of the disease.

Case 2.—A skin graft was taken from the chest for a plastic operation on the fingers. 24 hours later crysipelas developed about the raw surface on the chest; the skin graft also suppurated freely, but did not give rise to crysipelas. A scarification of the skin at the spreading edge of the rash produced a sarcina only. The pus from the raw surface on the chest yielded a pure growth of a streptococcus. This coccus was in every respect a typical streptococcus pyogenes, and was apparently inoculated by the surgeon into the superficial layers of the skin, producing crysipelas, and into the subcutaneous tissues of the fingers, producing suppuration only.

Case 22.—Osteomyelitis of the radius in a child was operated on and crysipelas arose round the wound seven days later. An abscess of the

CASE 22.—Osteomyelitis of the radius in a child was operated on and erysipelas arose round the wound seven days later. An abscess of the neck was opened three days before the onset of the erysipelas. Cultures from the bone abscess gave staphylococcus aureus, a diphtheroid bacillus, and a typical streptococcus pyogenes; from the neck abscess staphylococcus aureus, staphylococcus albus, and a typical streptococcus pyogenes were grown. In this case the aureus was no doubt the cause of the osteomyelitis and of the neck abscess. The streptococcus was introduced later into the arm and the neck civing rise to

coccus progenes were grown. In this case the aureus was no doubt the cause of the osteomyelitis and of the neck abscess. The streptococcus was introduced later into the arm and the neck, giving rise to erysipelas in the one place but not in the other.

CASE 26.—An abscess of the neck was opened and erysipelas developed some days later. Cultures from the bleb and from the abscess yleided a growth of staphylococcus albus and a typical streptococcus yogenes. This was the only instance in which a streptococcus was successfully cultivated from the contents of the bleb. In this case the abscess was supposed to have been caused by the albus and the streptococcus to have been introduced in a subsequent dressing.

CASE 28.—An appendix abscess was opened and some weeks later erysipelas developed around the still discharging sinus. Cultures from the sinus gave a growth of staphylococcus albus and a fairly typical streptococcus faccalis. It is possible that in this case the streptococcus faccalis was derived from the intestinal tract.

CASE 29.—A breaking-down carcinomatous gland of the neck was opened, and the wound was afterwards plugged in order to check secondary hæmorrhage; within 24 hours erysipelas developed. Cultures from the neck produced a diphtheroid bacilius and a typical pneumococus. This coccus was inoculated subcutaneously into a mouse which died four days later. Capsulated diplococi were present in the heartblood, and a pure culture of the pneumococcus obtained from the spleen. The breaking-down growth in the neck communicated with the buccal cavity, and it is possible that the pneumococcus causing the erysipelas was derived from the mouth and inoculated on to a raw surface at the time of the operation. The patient died, and a portion of the skin at the edge of the wound was removed at the poet-mortem examination, and sections showed necrosis and cedema of the epithelium, a marked cellular exudation around the blood-vessels, together with numerous bacilli and a few Gram-positive diplococi.

at the time of the operation. The patient died, and a portion of the sain at the edge of the wound was removed at the post-mortem examination, and sections showed necrosis and edema of the epithelium, a marked collular exudation around the blood-vessels, together with numerous bacilli and a few Gram-positive diplococci.

Case 49.—Cellido-cutaneous ervsipelas following a contusion of the elbow of three weeks standing. The fluid from a bleb contained large numbers of polynuclear cells. Cultures from a bleb grew the staphy-lococcus albus only. Cultures from a surgical incision yielded a pure culture of a somewhat unusual streptococcus approaching in type to the pneumococcus, but which we have classed as a streptococcus pyogenes. A portion of skin was removed at the operation and sections of this show clearly a typical acute inflammatory condition of the epidermis itself; the superficial layers of the epidermis are in places stripped up, forming spaces (or blebs) which contain large numbers of polynuclear cells. These sections are markeily different from those derived from the cases of acute cellulitis, unaccompanied by erysipelas.

Case 53.—A double osteotomy of the femors for rachitic curvatures was followed in three days by suppuration of both legs. The suppuration continued for some weeks, and erysipelas eventually supervened around the sinus in the left leg, the condition of the right leg remaining unaltered. Three days after the commencement of the erysipelas cultures were taken from the left leg and produced a staphylococcus aureus and a streptococcus. The following day cultures were taken also from the right leg and staphylococcus aureus and a streptococcus aureus and a streptococcus were again grown; about 24 hours later a typical attack of erysipelas arose around the sinus of the right leg. The streptococci derived from both legs were in every respect identical, and, although they acidified litmus mannite, and did not affect salicin, we have classified them as members of the streptococcus poyenes group, s

patient from her scalp to the puncture wound of the hypodormic needle.

CASE 57.—A wound in the neck of a child was followed by facial erysipelas. Cultures from the wound yielded staphylococcus albus and streptococcus gogenes. A culture from the streptococcus isolated was inoculated into two mice; in one case into the cellular tissues beneath the skin, in the other case into the scarlied epidermis itself. The mouse inoculated subcutaneously died in three days, and numerous streptococci were found to be present in films taken from the heart blood. Sections taken at the site of inoculation showed acute inflammation of the subepidermal cellular tissues, the epidermis itself being normal. The second mouse remained well and was killed four days after inoculation; nothing could be seen at the site of the scarlified skin and nothing abnormal was found in the sections of the epidermis in this situation; no organisms were found in the films of the heart blood.

The following tables (Tables I. and II.) give the full cultural characters of the streptococci isolated in the

The pneumococcus obtained from Case 29 gave the following cultural reactions:—Broth, general turbidity and granular deposit; agar, pin-point colonies; jelly slant, no growth; neutral red broth (anaerobically), green fluorescence; litmus glucose, acid; litmus maltose, acid; litmus mannite, nil; litmus glycerine, nil; litmus cane sugar, acid; litmus raffinose, acid; litmus erythrite, nil; litmus salicin, nil; litmus milk, acid and solid clot. In addition, a mouse was inoculated suboutaneously and died four days later. Capsulated diplococci were present in smears from the heart blood and a pure culture of the pneumococcus was obtained from the spleen.

Out of these 38 cases of erysipelas an organism of the streptococcus class was found to be present in 29 instances. In only one case, in which a wound was present, was no evidence of a streptococcus obtained either in the films or in cultures made from the wound; diplococci only were present in the films, and cultures yielded a profuse growth of the staphylococcus aureus. We regard this exception as due to a technical error and consider that a streptococcus was probably present but was not demonstrated owing to the abundant growth of the staphylococcus. In the remaining eight cases no wound was present, and it was only possible to obtain cultures either from a bleb or from the fluid obtained on scarifying the skin, and both of these appear to be most unfavourable materials for demonstrating the causative organism. That the abundant inflammatory exudate, usually present in the blebs, should so rarely produce a growth of the streptococcus was a somewhat unexpected occurrence, and on only one occasion was such a growth obtained; the explanation may be that these localised collections of serum possess bactericidal properties. In the 30 cases, therefore, in which a wound was present an organism of the streptococcus class was found on 29 occasions. Of these 29 strains six could not be isolated owing to the presence of other organisms. In 23 cases the full cultural characters of the organisms were obtained, and these have been grouped according to the classification of Andrewes and Horder-that is to say, 18 have been classed as members of the streptococcus pyogenes group, four as examples of the streptococcus fæcalis, and one as a pneumococcus. While it would, perhaps, be unwise to accept the classification of Andrewes and Horder as final, and to regard the streptococci which they have differentiated as true species, yet sufficient evidence is afforded that the various strains of streptococci can, on the basis of their cultural reactions, be divided into a few fairly definite groups, and that any member of each of these groups is

capable of retaining its special cultural reactions for many generations either outside the body or after its passage through animals. If, then, the streptococcus erysipelatis possessed any peculiar and established pathogenic properties, and if that streptococcus produced only erysipelas, we should expect to find that it possessed also peculiar and established cultural reactions. There is, however, we think, sufficient evidence that while the typical streptococcus pyogenes is the coccus most frequently met with in erysipelas, yet streptococci, which exhibit considerable cultural differences, and even pneumococci, are in a fair percentage of cases the causative organisms. Moreover, the variability of the organisms met with in erysipelas appears, as will be seen, to be closely comparable with that of the organisms present in cellulitis, a condition which has never enjoyed the distinction of being considered a specific disease. It has, however, been urged in favour of the specific character of erysipelas that the disease is transferred as such from one patient to another; yet while this undoubtedly does occur, as, indeed, one would expect, such evidence as we have been able to obtain shows it to be an event of considerable rarity. The subjoined tables (Tables III. and IV.) have been drawn up from the published hospital statistics concerning the incidence of erysipelas cases arising during the stay of patients in St. Thomas's Hospital. Only those instances of erysipelas arising round a pre-existing wound have been considered, as in these cases only were the statistics showing the incidence of erysipelas in surgical wards reliable. The inclusion of other cases, such as those of facial erysipelas, would, as a matter of fact, have made little difference in the statistical relationship between the number of beds and the number of instances of the disease in question. The average number of surgical beds was 264 and was distributed as follows: 240 in the general wards, and 24 in the septic wards. From 1896 to 1905 no attempt was made to isolate erysipelas cases from other cases admitted to the septic wards, but in 1906 six additional beds, in small isolation wards in the septic block, were added for the accommodation of erysipelas cases. This year is omitted from both tables since the arrangement was

made in the middle of 1906. In 1907 and 1908 we have the figures for a short period during which the erysipelas cases were isolated. A comparison of these two tables shows clearly that while the incidence of erysipelas is, as one would expect, greater in septic wards than in the general surgical wards, yet the separation of erysipelas from other septic cases has had no effect in lessening the occurrence of erysipelas in these septic wards.

The figures for the occurrence of erysipelas in the septic wards for 1908 include three cases which arose under the following circumstances. The erysipelas isolation wards being full, a girl with a sinus of buttock surrounded by a septic eczema was admitted to the female septic ward on Dec. 9th. On the following day, with no constitutional disturbance, there was an added, somewhat marginated, erythema over the buttock. This redness lasted only for 24 hours and did not spread beyond the buttock. The patient remained in the ward. On Dec. 18th two cases in the same ward, one with a wound due to necrosis of the jaw, and the other with a discharging retro-pharyngeal abscess, developed erysipelas around their wounds; they were transferred to the erysipelas ward. Subsequently a culture was taken from the sinus of buttock and this yielded a growth of a streptococcus, and the case was then regarded as having been one of erysipelas of a fleeting nature or an instance of a "septic rash." There was at the same time a case of facial

erysipelas in one of the two male septic wards because the male erysipelas ward was full, and in this ward no other cases of erysipelas arose. These two parallel cases go to prove that the danger of transmitted infection depends on the presence of discharge from a streptococcal wound rather than upon the risk of contagion from such a lesion as facial erysipelas, which is practically free from discharge. In this connexion it may also be noted that one or two cases of doubtful erythema were admitted direct to the special erysipelas ward, and the subsequent course of these cases proved that they were not suffering from erysipelas on admission, nor did they contract it, though exposed to infection, at any rate by aerial contagion.

With regard to the dressing of wounds in general, we may state that, as a rule, the dress-

ing used was plain sterilised gauze, though in some of the dirtier cases the gauze was wrung out in 1 in 40 carbolic before being applied to the

There is direct evidence that the same organism may produce at the one time erysipelas and at the other cellulitis, an experiment which was accidentally performed in one case in this series in which a streptococcus was introduced into two separate lesions, giving rise to local suppuration in one place and typical erysipelas in the other. In two other cases, however, the transference of the streptococcus from one erysipelas infection to another lesion in the same patient was followed by a second attack of erysipelas, an event which may be explained by the supposition that the point of entry of the organism was in each case the epidermis. The evidence of animal inoculation is certainly opposed to the view that the organisms of erysipelas possess any specific properties. The animal experiments performed in this investigation are not sufficiently numerous or definite to admit of any conclusions being drawn from them; in one instance, however, the organism isolated from a case of erysipelas produced cellulitis, septicæmia, and death in a mouse, but no erysipelas. McFarland states that: "When injected into animals Fehleisen's coccus behaves exactly like streptococcus pyogenes," and in another place, "If the cultures (of streptococcus pyogenes) be of moderate virulence

and the ear of a rabbit be carefully inoculated with a small quantity of a pure culture, local erysipelas usually resultsif, however, the streptococous be highly virulent, the rabbit dies of general septicæmia." That the varying lesions usually obtained by inoculating animals with streptococci from various sources do not necessarily depend upon the degree of virulence of the organism in each case is shown by the experiment referred to above, in which a mouse died from septicæmia with spreading cellulitis after the inoculation of a streptococcus into its subcutaneous tissues, whilst another mouse simultaneously inoculated by means of rubbing in a culture of the same streptococcus into the scarified skin escaped unharmed; the different effect in this case might reasonably be explained solely by the difference in the point of entry of the organism.

Erysipelas is commonly considered to be more infectious than cellulitis, and this may be due to the more superficial nature of the inflammation and to the desquamation which accompanies the former condition, but the danger of infection is the danger of transferring streptococci from one patient to another, a sufficiently serious event, of which perhaps the least serious effect is the production of erysipelas.

With regard to the mode of infection in these 38 cases of erysipelas, in 21 infection occurred outside the hospital, and in no instance was any history of exposure to infection

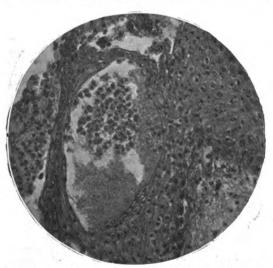

obtained; in many of the cases alone in seven cases. in some instances transferred

of facial erysipelas no obvious wound was present at the time of admission to the hospital, but some slight abrasion of the surface epithelium had doubtless taken place and subsequently healed. In 13 of these 21 cases in which streptococci were proved to be present other organisms were present in six cases, a streptococcus the 17 cases of erysipelas arising in the hospital, one was infected at an operation and yielded a pure culture of a streptococcus. In the remaining 16 cases streptococci were found to be present in 15, 13 times in company with other organisms, and twice only in pure culture. Many of these cases were infected with other pyogenic organisms at the time of operation and when suppuration commenced were to a "septic" ward, which

is now isolated from the erysipelas ward and nursed by a different staff. The preponderance of mixed infections in the hospital cases in contrast to the high percentage of pure infections in those cases arising outside the hospital is evidence of the comparative failure of aseptic precautions when dealing with a large number of various infections. The one hospital case in which no streptococcus was found was a case of facial erysipelas, without obvious lesion, arising in a female medical ward. A history of a previous attack of erysipelas was obtained in several instances in this series, and the extremely short period of immunity conferred by an attack was well shown in the cases of the two patients, in whom two separate outbreaks of erysipelas developed within a few days of the original attacks. It is worthy of note that while such streptococcal and pneumococcal infections as erysipelas, lobar pneumonia, and probably rheumatic fever are accompanied by but a brief period of immunity, and, indeed, actually predispose the patient to a second attack, yet scarlet fever, which is by some considered to be a streptococcal infection, frequently confers upon the patient a complete and life-long immunity.

A further point in the etiology of erysipelas, which was

particularly investigated in this series, was the exact site of the inflammatory processes, and it would seem that in this consists the main, if not the only, difference between this

Microphotograph (No. 2 eyeplece, ith inch objective). Section through centre of crysipelas "bleb" showing the collections of polynuclear leucocytes on the surface and within the layers of the epidermis. There is no cellular infiltration of the deeper structures.

⁷ McFarland: Text-book upon the Pathogenic Bacteria, 1906, p. 268.

condition and that of cellulitis. Owing to the fact that in the great majority of cases no indication for surgical incision arose, in only two instances could portions of the skin be obtained for microscopy, and in both of these the epidermis itself showed the histological characters typical of acute inflammation. Many cases, however, were accompanied by the formation of vesicles within the layers of the epidermis, and the cytological evidence of the fluid obtained from these yielded abundant evidence of the superficial site of the acute inflammation, the cells of the fluid in every instance consisting almost entirely of microphages and macrophages. In addition, in some cases in which blebs were absent similar cytological findings were obtained on scarifying the epidermis. The evidence that in erysipelas the condition is one of acute inflammation of the epidermis itself is in striking contrast to the histology of cellulitis, for although a clinical examination of the skin in cellulitis would appear to reveal

but it is improbable, at any rate in the cases in which the rash becomes generalised and resembles the eruption of scarlet fever, that the epidermis itself shares in the acute inflammation. The redness of the skin is probably due to a cutaneous dilation of the blood-vessels such as is present in the erythema of scarlet fever. Owing to the presence of other organisms the streptococcus could only be isolated in one of these cases; its cultural characters were as follows: Morphology, chains to 30; broth, clear fluid, granular deposit; agar, pin-point colonies; jelly, no growth; neutral red broth (anaerobically), abundant growth, no alteration of colour; litmus maltose, acid; litmus mannite, nil; litmus raffinose, acid; litmus salicin, nil; and litmus milk, acid, no clot.

Cellulitis cases. - Twelve of these cases were investigated altogether. They were chosen as typical cases of undoubted cellulitis and showed no clinical features of interest. The all the characters of an acute inflammation, yet examination | full cultural characters of the cocci isolated are given in the

of sections of the epidermis in this condition presents no evidence of any departure from the normal.

The treatment of erysipelas is somewhat outside the scope of this paper, but it may be mentioned that many of the cases were treated by some form of serum, and, on the whole, with very little effect, a result which may be in part explained by the probability that in many instances the serum employed was obtained by the immunisation of a horse with a streptococcus of different nature from the organism producing the erysipelas. In the only case in this series in which a chronic suppurative condition followed the acute attack of erysipelas, treatment by a vaccine prepared from the streptococcus obtained from the patient's tissues was promptly followed by marked improvement.

Cases of crythema of doubtful nature.—These cases, five in number, consisted of crythemata arising in connexion with septic wounds. In three instances the rash was generalised and the diagnosis of "surgical" scarlet fever was made. The first of these cases is included only as a control to the findings in the erysipelas cases. There was an erythema of the face without any constitutional symptoms. The serum obtained from an almost healed cutaneous wound in the erythematous area yielded no evidence of inflammation, nor was any pathogenic organism obtained from cultures taken from the fluid. In the remaining four cases an organism of the streptococcus class was obtained on three occasions, and a staphylococcus aureus in one case. In no case could a section of the skin be obtained, nor were any blebs present, and it is uncertain whether there was inflammation of the skin itself or not. It seems possible, however, that many of these "septic" rashes spreading from an infected wound are of an acute inflammatory nature and associated with organisms of the streptococcus class, to be present on 10 occasions, once an unusual coccus was

accompanying tables (Tables V., VI., and VII.), and the organisms are grouped in the same manner as in the erysipelas cases.

obtained, and once a staphylococcus aureus. In the case in which staphylococci only were present no incision was made and the cultures were taken only from a varicose ulcer which was the starting point of the cellulitis. In the 11 cases in which organisms of the streptococcus class were present the coccus was not isolated on one occasion owing to an air contamination; of the other 10 cases seven proved to be due to the streptococcus pyogenes, two to a streptococcus fæcalis, and one to an unclassified coccus. The cultural characters of the strains of streptococci obtained showed no typical variations by which they could be distinguished from the strains obtained in the erysipelas cases. Owing to the fact that an incision was necessary in the majority of cases, the streptococcus was frequently found in pure culture, and it was possible to obtain small portions of the skin for micro-scopy. Although all the clinical signs of acute inflammation were present in each case the only signs proper to the skin itself would appear to be those of redness and possibly heat, due no doubt to a dilatation of the cutaneous vessels. In all the sections examined no microscopical evidence was found of acute inflammation of the skin itself; the inflammatory exudate was confined to the subcutaneous tissues, and there was no invasion of the epidermis by polynuclear or other cells. Cases of acute cellulitis are usually accompanied by a considerable degree of fever and marked constitutional disturbance; if actual pus formation does not occur they run a rapid course, tending to recovery. Erysipelas and cellulitis appear to differ only in the effects which an acute inflammation of the skin would give on the one hand, and of the deeper tissues on the other. The epidermis is not a suitable tissue for the development of large abscess cavities within its substance, but the formation of cuticular "blebs" filled with an acute inflammatory exudate is comparable with the larger pockets of pus frequently met with in the subcutaneous tissues in cellulitis.

Lymphangitis cases.—Five only of these cases were examined and they were clinically chosen as typical instances of the disease. In each case a pure culture (if the additional presence of a diphtheroid bacillus on one occasion be excepted) of the staphylococcus aureus was obtained. The full cultural characters of four of the staphylococci obtained were investigated, but these differ in no way from those of similar organisms isolated from other pathological conditions, with the exception that no clot was produced in milk in any case. Table VIII. shows the cultural properties of the cocci examined.

A portion of the reddened skin was removed on one occasion and no evidence of acute inflammation was found in it. Cases of lymphangitis usually present a longer incubation period and less severe constitutional disturbances than are customary in erysipelas or cellulitis, and in accordance with this they and if the application of Gordon's tests be allowed as a would appear to be usually caused by an organism of different means of differentiating the various species of streptococci,

type and less severity. Lymphangitis can, as a rule, only be diagnosed in its early stages, in which the subcutaneous red lines of the inflamed lymphatics are seen to connect the primary lesion with the enlarged, and often suppurating, collections of glands. Staphylococci are particularly liable to spread by the lymphatic circulation and streptococci by

direct continuity, so that in infections by the former organism glandular involvement is almost invariable, while in acute streptococcal infections the glands frequently escape. Hence, either glandular enlargement or the presence of a staphylococcus would be in favour of the diagnosis of lymphangitis rather than cellulitis.

Résumé.—The objection that all the cases selected for cultural investigation were not really erysipelas must, of course, be met, but the examples chosen were characterised by most of the accepted clinical signs of cutaneous erysipelas that is to say, in nearly all of them there was a shiny red cedema of the skin with well-defined edge, and the presence of vesicles on the cutaneous surface, accompanied in most instances by constitutional symptoms of fever, headache, anorexia with initial vomiting, and, not infrequently, shivering or an actual rigor. It was, however, discovered at an early period of this investigation that the certainty of diagnosis of erysipelas rested on three groups of phenomena -namely, such physical signs as have been mentioned above, constitutional disturbance, and the local spread of the erythema with its growing margin, and of these the last appears to be the most constant feature in streptococcal infections of the skin. Vomiting or shivering may be absent in cases which present the typical skin lesion of erysipelas, while in a few of our cases of cellulitis these severe constitutional disturbances occurred—cases which yielded a growth of a streptococcus but which showed no inflammation of the epidermis. Fever, as a rule, was much more marked in the typical erysipelas cases than in those of cellulitis, even where a quantity of pus was shut in and required evacuation by the knife, but there were several cases with initial vomiting and a characteristic spreading red rash, in which the temperature was never higher than 100° F., as taken in the mouth. The conclusion at which we arrived, therefore, was that the most constant and reliable phenomenon on which a diagnosis of erysipelas could be based was the spread of the erythema from a local focus, this spread of infection being characterised by true inflammation of the epidermis with exudation of leucocytes, and not merely a transitory erythema due to vascular dilatation, such as occurs in cellulitis and lymphangitis.

Erysipelas, then, may be caused by a variety of organisms,

it would appear that a considerable percentage of cases are produced by organisms other than the streptococcus pyogenes. The organisms isolated from the cases of erysipelas vary on lines comparable with those obtained from cases of cellulitis; nor are any particular cultural properties found in organisms obtained from the one disease and not in those derived from the other. In one instance both local suppuration and typical erysipelas were produced in the same patient by the same streptococcus, an event in accordance with the results obtained in some instances of animal inoculation. The main difference between erysipelas and cellulitis would seem to depend, not upon the virulence of the causative organism, but upon the actual site of the lesion; in erysipelas there is invariably acute inflammation of the epidermis itself; in cellulitis deeper tissues are involved and the epidermis escapes. The period of immunity conferred by an attack of erysipelas is extremely short, and it would appear either that one person is more liable to the infection than another, or that one attack actually predisposes to a second. The course of acute erysipelas would seem at present to be little influenced by serum therapy, and it is possible that a better result might be obtained by the accurate method of obtaining the appropriate serum in each infection, if such a proceeding were practicable. In the few cases of erythemata other than erysipelas examined an organism of the streptococcus class was commonly present in the local wound. In the five cases of lymphangitis examined a typical staphylococcus aureus was obtained in each instance.

In conclusion, we would define erysipelas as an acute inflammation of the epidermis due to the presence of one of the organisms of the streptococcus class, of which the streptococcus pyogenes is the most frequent example. Cellulitis appears to be a strictly comparable inflammation of the cellular tissues, and when the inflammatory processes involve both the epidermis and the cellular tissues the condition of cellulo-cutaneous erysipelas results. Acute lymphangitis would seem to be a less virulent infection due, as a rule, to organisms of the staphylococcus class, with a greater tendency to spread, as its name implies, by the lymphatic system. Erysipelas is not, in the true sense of the term, a specific disease, since it may be produced by a variety of organisms, and these organisms are capable of producing other diseases in other parts of the body.

In the shortness of its incubation period, in the acuteness of its onset-often with marked constitutional disturbances, in its course, in its usual tendency to early and spontaneous cure, and in the nature of the immunity which it confers, erysipelas presents a striking parallel to both acute cellulitis without local suppuration and to acute lobar pneumonia. Nor is it surprising that such similar diseases should all be due, as a rule, to organisms of the same class, the differences in the effect of each disease to the individual being caused by the differences in the localities attacked. It has long been recognised that acute lobar pneumonia may be produced not only by the pneumococcus but also by other similar organisms, such as the streptococcus pyogenes, and that the pneumococcus is capable of effecting an entry and producing disease in other localities than the lung, and we believe that an extension of similar views to the nature of erysipelas constitutes the true etiology of the disease.

We have to thank the members of the staff of St. Thomas's Hospital for permission to make use of their cases.

THE WORSHIPFUL COMPANY OF PLUMBERS.—The Lord Mayor-elect, Sir John Knill, Bart., was duly sworn into office as Master of the Worshipful Company of Plumbers at the quarterly meeting of the Court at Guildhall on Sept. 30th. Before vacating the chair the late Master, Mr. Adrian Pollock, made an interesting presentation to Mr. Charles Hudson. Past Master and present Renter Warden of the Company, of a copy of a water-colour drawing, showing a view of the old Plumbers' Hall, pulled down to make way for Cannon-street Station. Mr. Hudson is the oldest surviving member of the Court, having taken up his freedom and livery in the old hall in 1854. A committee was appointed to examine the note-books and drawings of the plumber apprentices attending the technical classes whose names appear on the Company's register of indentured apprentices.

A CASE OF SYPHILITIC "REINFECTION' NINE YEARS AFTER, WITH SOME REMARKS ON SYPHILITIC "IMMUNITY"

AND A NOTE ON TREATMENT.

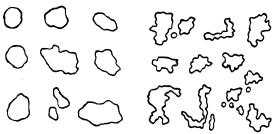

BY HENRI DARDENNE, M.D. EDIN., M.R.C.P. LOND.,
PHYSICIAN TO THE FRENCH HOSPITAL AND THE FRENCH
EMBASSY IN LONDON.

In May, 1897, I was consulted by a gentleman for what he called a slight irritation of the penis. He had, he said, never been ill before. On April 10th of the same year he had had connexion, and on May 9th he noticed a slight sore in one of the fossæ of the frænum. On examination I detected a small superficial ulcer in the left fossa. By gently "dipping" the index and thumb and lifting the sore from the subjacent tissues a distinct indurated base could be felt. His inguinal glands were swollen, hard, indolent, and four or five could be felt in each groin. They were characteristic. Hard chancres in that region have two distinct peculiarities: (1) they are, of course, small and crescentic or fissure-like; and (2) the induration at their base has to be looked for in the manner I mentioned above. I at once put him under mercurial treatment and appropriate remedies were applied locally. The chancre healed within three weeks. Six weeks afterwards he developed a typical roseolous rash affecting chiefly the chest, the abdomen, and the inside of both thighs. His throat was congested and mucous patches were to be found on both tonsils and under the tip of the tongue. He consulted Professor Fournier of Paris, who corroborated the diagnosis and also approved of the treatment he was having. The symptoms rapidly subsided and within a few months he was absolutely free from all secondary manifestations. He was very regular in his attendance for over three years. I then lost sight of him until June 18th, 1906, when he again told me that he was very much troubled with another sore of the penis. On examination this proved to be a small circular ulcer about a quarter of an inch in diameter, situated on the dorsal aspect of the coronal fissure. The base was indurated and this distinctly so. The inguinal glands in both groins were characteristic of a syphilitic adenopathy. He had had connexion of a suspicious nature about five weeks previously, and he told me that he had never suffered from any syphilitic "reminders" since I last saw him in 1901. The ulceration healed within 18 days and the glands diminished gradually in size. In July he again developed a copious roscola, and again his buccal mucous membranes became affected. The scalp this time became the seat of a few irritating papules. These secondary symptoms were the exact repetition of what he suffered in 1897. The same treatment was again prescribed and this until quite recently.

According to the very great majority of authorities reinfection with the syphilitic virus is possible. Sir Jonathan Hutchinson relates at some length the case of a young surgeon who contracted syphilis in 1860 and who was treated by him with large doses of mercury. In 1865 he again contracted a chancre which indurated and was followed again in due course with a distinct roseola and fresh mucous patches on both tonsils. The same patient, curiously enough, suffered from two attacks of small-pox. Rodet mentions two cases, and in these the interval between the first and second infection was four and eight years respectively. Dr. L. Hardie mentions a case, also in a surgeon, who 11 years after the first infection contracted a second chancre which was followed after a few weeks by typical secondary symptoms. All the cases published by Diday are open to caution, for, according to him, the secondary symptoms do not appear after a second infection, but are followed within a short time by gummas, nodes, and deep serpiginous ulcerations, lesions which are tertiary and may simply be the manifestations of the primary infection. Personally, I must say, though it has been my lot for the last 16 years to see and to treat, both in my hospital and private practices, several thousand syphilitic patients, that it is my first experience of such a case.

We must be most careful not to confound a true syphilitic reinfection, whose pancity in numbers only proves the absolute rarity of such cases, with what Professor Fournier calls

"late syphilitic secondaries," such as erosions of the penis, the vulva, and the lips. A recurring roseola, such a roseola appearing 8 and 10 times in the same patient, and this up to the eighth, ninth, and tenth year after the primary infection, may also be a source of error. A gumma of the penis, and above all a herpetic affection where caustic has been used by the patient, may be at times exceedingly nas been used by the patient, may be at times exceedingly puzzling. We all know that in herpes the base is not indurated, the inguinal glands are not affected, or, when so, only to a slight extent, and they lack the features of the syphilitic adenopathy. Polycyclism and microcyclism are the only diagnostic signs between herpes and a Hunterian chancre. The contour of a syphilitic chancre is either circular, ovoid, or crescentic, and more or less regular. On the contrary on examining and more or less regular. On the contrary, on examining with a pocket lens a herpetic lesion sufficiently extensive, the contour is noted to be irregular and geographic-like in outline, and this as if several segments of a minute circumference had actually joined together (polycyclism). These segments are all parts of small circles (microcyclism), like what the segments of a pin's head would be. These two signs are pathognomonic of herpes. The syphilitic chancre, being as a rule a solitary lesion, cannot, obviously enough, give the aspect of a compound one such as herpes. The diagram below speaks for itself. And lastly, in herpes the

Contour of hard chancre.

Contour of herpes vesicles.

erosions are very small, multiple, irregular, and at times disseminated. They are also more superficial, heal more rapidly, and this without leaving any induration.

Hard chancre must not be mistaken for the soft ones. The

soft is, as a rule, multiple and is a distinct ulcer. The syphilitic is usually solitary and a mere erosion. It has no special borders as are usually described in text-books, but on the contrary is on the same level as the adjacent tissues. It has not the proper suppuration of the soft one, and its base is indurated in a manner characteristic of its locality. The glands in the hard chancre are indolent and have no tendency to suppuration. In the soft one the adjacent glands may not be affected at all or there might be only one which is swollen, painful, and very prone to suppuration. The hard chancre is very rarely auto-inoculable, but one chancre may appear within a few days after the other (successive chancre) and be mistaken for an instance of auto-inoculation.

My excuse for going so deeply into these different diagnostic features, which may appear out of place, is simply to show the care I took not to mistake one of them for a reinfection with a hard chancre. Lately a great scientist in this country said: "We know that one attack of syphilis confers immunity during the rest of the individual's life.' The case just related, and a few others which one feels bound to consider as authentic, are in direct contradiction to this statement. We gather that the chief feature of immunity in syphilis is its coexistence with the presence of an active virus in the organism which may confer a refractory state to the skin and mucous membrane to the attacks of the external treponemes. This skin and mucous immunity, however, may not be general and absolute. In vaccination the whole skin may become refractory, yet the cornea may not be so, or one cornea may have become immune and the other not. Most important of all are the experiments of Finger and Landsteiner on men, and according to them there is no absolute immunity in syphilis, and this either in the primary, secondary, or tertiary stages. The majority of syphilitics react in a specific manner to the virus, and this in proportion to the quantity of the virus which they ingeniously injected in subcutaneous pouches. Those in the tertiary stage, as a rule, reacted in a special manner when inoculated with virus taken

from primary or secondary lesions. At the seat of inoculation erythematous patches were formed with a distinct circumscribed hard base. From the foregoing we may conclude that (1) immunity in syphilis is not absolute, but only a relative one; (2) reinfection is possible under certain circumstances even when the tissues are not absolutely sterilised.

Treatment.—The percentage of 3 to 5 of the syphilitic patients developing late formidable tertiary lesions after careful treatment is the result of statistics some 20 years old, and with our better knowledge of the disease this could further, no doubt, be reduced. A long course of treatment is, perhaps, the only means we actually possess to effect this. Every mode of treatment I consider to be insufficient if it has not lasted at least four years. As an example, take 100 cases of general paralysis. In 95 it has occurred in those who have had an insufficiently long treatment-about a year or so-and in only about five of those who had undergone one of at least three years duration. The same result applies to tabes. These figures are the best mathematical arguments in favour of a long course of mercury. Mercurialisation in syphilis can, as Professor Fournier very lately said, be compared to vaccination. The first is a preventive which no one can doubt against the very vast majority of possible future syphilitic manifestations, but, like vaccination, it is only a temporary one, the syphilitics having to be "remercurialised" in order again to become relatively immune for a time more or less long against the influence of the syphilitic virus.

The treatment, according to the same great authority, could be divided into different stages: (1) Immediately after infection a course of mercury lasting for at least two years, and this whether the patient is troubled with reminders or not; (2) a second course lasting the whole of the fifth year; (3) another course of mercurial treatment lasting part of the seventh and eighth year. This, of course, has to be modified according to circumstances and individual peculiarities. Personally, I consider it a perfect heresy to say that two years of mercury is a sufficiently adequate one. It may be enough for the present, but what about the future? How many cases of syphilis have we not all seen who after having been treated according to the most modern methods for this brief period have come to us again after a few years the victims of the most formidable tertiary lesions! Yet they were considered cured and their case a mild one! Patients with mild secondary symptoms, though it may seem paradoxical to say so, are the worst ones, and the reason for this is because, once they are no longer troubled with any outward manifestation of the disease, they, as a rule, abandon all further treatment. On the other hand, those who are afflicted with constant, troublesome, and repeated "reminders lasting a few years and necessitating constant treatment, have more chances to escape the tertiary manifestations and also the formidable so-called parasyphilitic affections. The relative immunity conferred by a mercurial course of treatment is, as I have said already, but temporary. The case of Tushmann corroborates this to the fullest extent. briefly that of a syphilitic woman becoming pregnant seven times. She is not during all this time treated, and each time she gives birth to a syphilitic child. Becoming pregnant for the eighth and ninth time, she undergoes a most energetic course of mercury and has then the satisfaction each time of giving birth to a healthy child. For the tenth time she again becomes pregnant, neglects all treatment as she was considered cured, and once more gives birth to a syphilitic infant who dies at the sixth month. Finally, she is pregnant for the eleventh time, undergoes a course of treatment, and again gives birth to a healthy child. This case needs no comments.

Again, we know that general paralysis, which is the most dreaded syphilitic tertiary manifestation, and all the more so as it is incurable, is most prevalent between the seventh and the twelfth year after infection. Would it not be possible to a certain extent, by a rigorous course of treatment during the fifth and seventh year of the disease to reduce the percentage of those unfortunates who fall victims to that dreadful calamity? It would, at all events, be worth our while to try it and thus give the benefit of the faintest possible chance to our patients. It would certainly be better than telling them that they are "cured" or apparently so for all purposes, after a course of two short years of treatment. They then neglect all the hygienic rules that a syphilitic, I consider, should at all times observe and continue to observe. Let me then again repeat, however trying it may be, that the best safeguard, in fact, the only safeguard, which a syphilitic can possibly have to avoid these irreparable catastrophes, resides, and resides alone, in a long course of treatment which has been methodically carried out, and this at frequent and successive intervals extending over a period of several years. Immunity in syphilis has only a relative signification. It does not, in the least, imply an absolute cure. Mercury, and mercury alone, can, just like vaccination in small-pox, confer a temporary immunity, more or less long, against the specific virus which is in the organism, and which at any time can reveal its existence by inducing fresh syphilitic manifestations; this, at the same time, conferring a relative refrac-tory condition to the skin and mucous membrane against possible reinfection, though reinfection can take place again in tissues which are far from being absolutely sterilised—

i.e., free from all specific treponemes. It is not, therefore, in the least an absolute proof when it takes place again that the patient at the time of reinfection is absolutely free from all specific organisms. We may consider it as a possibility, but not as an absolute certainty.

For these reasons it is just as necessary, if not more, for a syphilitic to undergo a fresh course of "remercurialisation" at successive and even distant intervals as it is for anyone of us at times to be revaccinated. It is, at all events, the only means that we possess at present to secure a more or less

temporary relative immunity to the syphilitic, and thus guard him against the noxious effects of the treponemes of his infected tissues. For, with our present knowledge, we must candidly admit, that we cannot, and ought not to, give a definite answer to the syphilitic when we are asked by him whether he is cured or not, no matter how energetic, long, and scientific the treatment has been. Personally, I have no hesitation in saying that the more I see of syphilis the less inclined I feel to give a positive answer, lest the patient may come back to me at some future time the unfortunate victim of some severe syphilitic manifestation, and thus be the living contradiction to a too optimistic and scientifically unfounded

assertion. This has certainly been the experience, so far, of the vast majority of those among us who have had much to do with syphilis and its special study.

Albany-street, N.W.

A CORNEO-CONJUNCTIVAL BRIDGE: A NEW METHOD OF CATARACT EXTRACTION.

BY NEVEN GORDON CLUCKIE, M.B. GLASG.. OPHTHALMIC SURGEON TO THE GREENOCK EYE INFIRMARY AND THE ROYAL VIOTORIA EYE INFIRMARY, PAISLEY.

SINCE the introduction, about half a century ago, of yon Graefe's method of extracting the lens by linear incision, ophthalmic surgeons as a rule have been content to perform their cataract operations under the conditions laid down by that distinguished surgeon, believing his operation to be the safest and most successful under all circumstances. There are few, however, but will admit that even under the most favourable conditions this method has certain imperfections which expose the result to undesirable complications, the greatest of these being the sudden removal of all nourishment from fully one-third of the cornea, whereby union is delayed and resistance to possible microbic infection is diminished. Many attempts, indeed, have been made to combat these defects, but von Graefe's operation to-day occupies the position that it did on its introduction into ophthalmic surgery. Any improvement which will reduce these risks of infection and the danger of non-union of these delicate structures is of the greatest importance. that end in view, I desire to bring under the notice of ophthalmologists a modification of von Graefe's operation which has given me highly satisfactory results.

It is well known that the present operation for extraction of cataract consists in making a complete section of the cornea through its upper segment. While successful in many cases, it is liable in others to be followed by disastrous results. The modification to which I would direct attention consists in performing von Graefe's operation up to a point that leaves a connecting flap between the cornea and the conjunctiva

about four millimetres broad. Instead, then, of completing the corneal section in the usual fashion, the Graefe's knife is Instead, then, of completing carried further up under the bulbar conjunctiva for from 10 to 12 millimetres and is then withdrawn without cutting through the conjunctiva. We thus have a corneo-conjunctival bridge, which may be broad or narrow, but the broader and longer the conjunctival attachment to the cornea, the greater the chances of success and speedy recovery.

The object in having a large corneo-conjunctival band is to allow of sufficient bulging or gaping of the wound to take place, so that when pressure is applied by a Daviel's spoon on the lower part of the cornea the wound opens sufficiently to allow of the exit of the lens and to close immediately pressure is withdrawn. If the surgeon desires to perform iridectomy at this stage it is best done upwards and inwards; the capsule of the lens may be ruptured either before or after the iridectomy from the temporal side. By these means the operator will feel that he has complete command of the eye, no matter how nervous or restless his patient may be.

I claim that by means of this corneo-conjunctival bridge, the continuity between the cornea and the conjunctiva being maintained, the nourishment of the cornea is not interfered with to the same extent as in the usual method, where complete division is carried out. Moreover, the parts are kept in more accurate apposition, thereby favouring rapid and certain union. From this it follows that the anterior chamber

will be re-established in a shorter period.

The risk of the edge of the upper eyelid getting between the lips of the wound during the operation, or the conjunctival flap turning in upon itself and being caught in the wound, as sometimes happens, is under this method impossible. The likelihood of the iris, the vitreous, or the cortical substance being held in the wound is less likely to occur from the fact that the "bridge" gives greater freedom for thorough examination. In sickness from shock, in local and general anæsthesia, the "bridge" would act as a safe barrier in preventing the usual prolapses. Suturing the lips of the wound I have never seen, nor do I believe in, but such would be unnecessary with the "bridge." astigmatism would be less likely to be produced.

In conclusion, should there be any difficulty in the extraction of the lens, by this corneo-conjunctival bridge method the operator can complete his section, as in the ordinary von Graefe's operation, by the aid of a pair of fine scissors. He can snip through the band of conjunctiva and proceed in the usual way to deliver the lens; but such proceedings in the hands of an expert will be found quite unnecessary. There is no deviation from the usual aftertreatment, but I may remark that in cases operated on by this method the eye may be examined minutely with less risk of doing harm. As I have had the best possible results in all my cases, embracing, as they do, glaucomatous cataract, with fluid vitreous, immature and senile cataract, I have every confidence in submitting the foregoing facts and believe that they will be found of the greatest value in cataract operations.

Greenock.

Fraudulent Dealers in Food.—At the Marylebone police-court recently five tradesmen in the district were punished by fines amounting to nearly £20 for offences under the Margarine Act, a penalty of £7 being inflicted in the worst case. From the evidence given and from the observations of the magistrate it may be concluded that the public do not detect that margarine is not butter because it is coloured to resemble it, and that by selling margarine as butter a profit of 50 to 60 per cent. is realised by the tradesman; that legislation forbidding the colouring of margarine would injure "trade" by warning a section of the public who would not buy or care to eat a fat which proclaimed itself as derived from sources other than the dairy; that the extent to which margarine is passed off as butter is considerable, amounting, according to the evidence of a Marylebone inspector, to about seven cases out of every 40 samples taken by him for analysis. The Marylebone borough council is to be congratulated upon its effort to put a stop to this fraud upon the public, and especially so because it is practised chiefly upon the poorer section of the community under its care which can ill afford to swell the profits of dishonest dealers by paying nearly double the value of the wares purchased.

Clinical Aotes:

MEDICAL, SURGICAL, OBSTETRICAL, AND THERAPEUTICAL.

A CASE OF HENOCH'S PURPURA; LAPAROTOMY; RECOVERY.

BY F. C. PYBUS, M.B., B.S. DURH., F.R.C.S. ENG., LATE HOUSE SURGEON, ROYAL VICTORIA INFIRMARY, NEWCASTLE-ON-TYNE.

This case presents features worthy of publication. A girl was admitted to the Royal Victoria Infirmary for severe abdominal pains of an intermittent character, of a week's duration, and the passage of frequent liquid bloody stools. At first sight intussusception appeared the probable diagnosis. On further examination there was no vomiting; the child did not appear very ill. The stools contained no mucus, but were made up of liquid fæces and brownish blood. No tumour could be palpated in the abdomen, which was quite flaccid. Œdematous patches were found at various regions of the body. A diagnosis of urticaria of the mesentery and a portion of the intestine was made. The patient was watched for 24 hours; at the end of this time, no improvement being found, the abdomen was opened, displaying several inches of congested and cedematous small intestine. The abdomen was closed after examining the remainder of the bowel. Some days later a purpuric eruption appeared on the arms and legs, disclosing the true nature of the condition. The notes of the case are as follows.

The patient, who was a girl, aged nine years, was admitted on Dec. 5th, 1907, for pains in the abdomen. A week before admission she came home from school at midday complaining of a pain in the abdomen near the umbilicus and passing into the back. She was given a dose of "composition" and returned to school in the afternoon. The pains were much worse at night. Next day the patient was seen by a medical man and fomentations were applied to the abdomen. The following day the hands appeared swollen but no change of colour was noted. The next day the patient had a dose of castor oil; the swelling of the hands disappeared, but patches of ædema appeared on the shoulders. For the next four days the patient still had abdominal pains, was given further doses of castor oil, and more swellings appeared on the back. On the day of admission several bloody stools were passed.

On admission the temperature was normal and the pulse was 140. The child had flushed cheeks and cedema round the left eye and side of the nose. She was very restless and had diarrhoea. On Dec. 6th she had regular abdominal pains occurring every few minutes, during which time she sat up in bed, cried out, and pressed both hands over the abdomen. Slight cedema was present round the left eye; no other skin lesions were found. There was no vomiting. Nothing of importance was ascertained in the previous or the family history. On examination of the abdomen no distension or peristalsis was seen. There was slight tenderness over the lower half of the abdomen, but no rigidity, mass, or peristalsis was felt. Nothing abnormal was noted per rectum. The urine contained a faint trace of albumin. There was frequent passage of faces, which were composed of a brown watery basis with altered blood, with no definite mucus, and were not foul-smelling. The patient was seen some hours later and was in the same condition. Solution of morphia (miii.) was given.

A diagnosis of urticaria of the mesentery was made, for the reasons mentioned above, and the patient was carefully watched. On Dec. 7th the patient was not quite so well. The abdomen appeared a little fuller and there was thought to be increased tenderness. It was decided to explore the abdomen.

The operation was undertaken by Mr. W. G. Richardson. The patient was anæsthetised with chloroform and the abdomen was opened in the middle line below the unbilitus. On examining the small intestine a section about eight inches long, and situated towards the lower end of the ileum, was found thickened, cedematous, and slightly altered in colour, and clearly marked off from the normal bowel on either side. The corresponding segment of mesentery appeared cedematous. The remainder of the intestine was examined, but nothing abnormal was found. The abdomen was then closed in layers. After the operation the patient

was somewhat eased, but the attacks of pain continued of the same character, and the diarrhosa and passage of blood still persisted. A week after the operation a crop of purpuric spots appeared on the extensor surfaces of both legs and forearms, and two days later the eruption had extended from the legs on to the buttocks. The gums were normal. Periosteal swellings were found on the front of both tibise. For the next fortnight the purpuric spots continued to appear in successive crops at intervals of a few days. At the end of this time no further eruption appeared and the stools were free from blood. The pains gradually became less severe and frequent and finally subsided. The patient left the hospital apparently well on Feb. 8th, 1908. Subsequent inquiry six months later showed that she was in normal health.

The case shows the difficulty in distinguishing vascular lesions of the intestine from mechanical obstruction, and particularly intussusception. The appearance of the intestine was quite compatible with early intussusception having spontaneously become reduced. The case also illustrates the relationship of urticaria and purpura. There must always be considerable difficulty in diagnosis, seeing that Henoch's purpura and intussusception may co-exist and that a portion of adematous bowel may be the exciting cause of increased peristalsis and lead to the formation of an intussusception. I have to thank Mr. Richardson for permission to publish this case.

A CASE OF HIRSHBERG'S FEBRILE INFECTION. By CLAUDE STONGIPHER. M.D.

In several scientific papers Dr. Leonard K. Hirshberg of Johns Hopkins has reported a series of infectious febrile diseases caused by other organisms than the typhoid and paratyphoid varieties of bacteria. In a private communication Dr. Samuel Darling of the Ancon Hospital, Panama Canal Zone, also mentions a number of organisms isolated from Hirshberg's febrile disease. He mentions the bacillus enteriditis, B. lactis aerogenes, and several varieties which cause diseases in animals. Hirshberg in his classic description mentions the following as features of the disease:
(1) Failure of the blood to agglutinate with the usual organisms such as B. typhosus, B. coli, and B. paratyphosus; (2) absence of relapses; (3) absence of hæmorrhages; (4) absence of phlebitis; (5) absence of rose spots; (6) absence of splenic enlargement; (7) absence of mortality; (8) absence of length period of incubation and prodromes; (9) presence of constipation except when the patient is fed upon raw milk diet; and (10) normal blood picture as regards hæmoglobin, erythrocytes, and leucocytes. The following case is reported through the courtesy of Dr. Henry Flood, in whose service it occurred.

An unmarried female, aged 22 years, was admitted to hospital on June 4th, 1909. Her health had been fairly good, and the personal history was negative except for an attack of measles and tonsillitis. The present illness began five days previously, when she missed her period, and awoke on the following day feeling languid. On June 2nd she complained of headache and constipation. Her mother summoned a physician, who said that the temperature was 104° F. On admission the patient had no appetite, felt languid, complained of severe, dull headache, and had griping pains in the abdomen. She was well nourished, the physical signs were normal, the blood examination was negative, and no abdominal tenderness or rigidity was noted. The facies was flushed and dull. The tongue was dry and heavily furred with a white, patchy coat. The temperature was 102.6°. There was no increase in the splenic or the liver dulness, and these organs were not palpable. Agglutination was absent with the five organisms named below. No rose spots were present, although one consultant insisted upon a provisional diagnosis of typhoid fever. A milk diet started a diarrhosa which lasted five days-i.e., until the milk was stopped. The temperature kept near 102 2° for 17 days; then it slowly fell and on the eighteenth day was normal. Recovery was uneventful. Agglutination tests were made with two 24-hours old typhoid cultures and with one bacillus lactis aerogenes, one paratyphoid, and one colon culture.

This case is particularly interesting, because it accords exactly with the 27 cases so far reported of Hirshberg's infection and absolutely fits in with none of the other fevers.

Rebiebs and Notices of Books.

Severest Anamias: Their Infective Nature, Diagnosis, and Treatment. By WILLIAM HUNTER, M.D. Edin., F.R.O.P. Lond.; Physician and Lecturer on General Pathology and Morbid Anatomy, Charing Cross Hospital; Physician to the London Fever Hospital. Vol. I., with historical schemes, charts, and plates. London: Macmillan and Co., Limited. 1909. Pp. 226. Price 10s. net.

The difficult subject of the causation, pathology, and treatment of the grave and severe forms of anæmia is one which Dr. William Hunter has made peculiarly his own, and we have on more than one occasion expressed our admiration for the services he has rendered to pathology and to practical medicine by his studies, many of which have appeared in controllarms.

In the volume before us he gives a detailed historical account of the various opinions which have been put forward in regard to the more profound degrees of anæmia, particularly that form which has usually been called in this country pernicious anemia, a name which Dr. Hunter strongly deprecates and which he urges should no longer be employed on the dual grounds of the confusion which exists in regard to its connotation and of the effect of such a term upon the patient as applied to the condition from which he is suffering. He traces much of the confusion to the well-known paper of Biermer published in 1871, in which the term progressive pernicious anæmia was first used. This term was afterwards applied, especially by German authorities, to a heterogeneous collection of grave anæmias with more or less obvious causes, among them being included the peculiar idiopathic anæmia described by Combe in 1822 and by Addison in 1849. Dr. Hunter establishes the unquestionable priority of the English description of this form of the disease. The general trend of his own work carried out during the past 23 years has been to establish this form as a nosological entity, to which he would now apply the name of Addisonian anæmia. He regards it as a specific infective disease with a typical mode of onset and a definite site of infection. He has also separated a group of severe and progressive anæmias due to the influence of septic conditions which he distinguishes as septic anæmias. Those he is to deal with in the second volume.

Dr. Hunter's contention in regard to Addisonian anæmia is, in brief, that it is a specific infective disease of hæmolytic nature, and that in addition to the anæmia the glossitic. gastro-intestinal, hæmolytic, febrile, and nervous features which he describes are important and characteristic and are the result of the infective agent, and are not to be regarded as secondary effects of the anemia. Dr. Hunter's work on the hemolytic changes in this form of anemia is too well known and recognised to need any discussion here; the object of his more recent work is to establish the infective character of the glossitic and other lesions associated with Addisonian anæmia. The glossitis he describes is, he maintains, not due to oral sepsis, although it is aggravated by it. Oral sepsis being so frequently present in Addisonian anemia leads to a complication of that condition by an intense "septic amemia" which constitutes a grave handicap to the patient. Dr. Hunter states that the effects of the two conditions upon the bone marrow are entirely different. The Addisonian anæmia heads to hyperplastic and regenerative changes, while the "septic anemia" is depressant to these functions and leads to aplastic changes. He urges that if the conditions leading to the septis complications are removed the prognosis of Addisonian anæmia is improved. The glossitic changes are

described as of varying intensity in different cases: sometimes of an acute and subacute inflammatory character, followed later by degenerative and atrophic changes; at other times more chronic. This glossitis may be one of the chief sources of complaint on the part of the patient, and may be characterised by great tenderness. It is an early rather than a terminal feature, and may be an early indication of relapse. In three cases examined bacteriologically the streptococous longus was isolated in pure culture. The changes in the stomach are a gastritis leading eventually to gastric atrophy, while in the intestine there may be a marked croupous enteritis, patches of congestion and catarrh, follicular enlargement, and patchy colitis. Several plates illustrate the macroscopic and microscopic appearances of these various lesions. Several tables are given detailing the incidence of the glossitic and gastro-intestinal lesions, but we cannot but feel that Dr. Hunter's account would have been of greater value if more detailed descriptions of the glossitic lesions had been given.

He next discusses in detail the pathological changes in the bone marrow, which have been so clearly and carefully studied by Professor R. Muir. On the basis of the changes in the bone marrow and of the characters of the blood. more especially as regards the occurrence of nucleated red corpuscles, Ehrlich has classified anæmias into normoblastic and megaloblastic, the former including the simple anæmias, the latter the more severe-practically, indeed, the whole group to which in Germany the name of Biermer's anæmia is applied. On this view the changes in the bone marrow are regarded as primary, and Addisonian anæmia included as one form—the pathological basis being a megaloblastic degeneration of the bone marrow. This view Dr. Hunter most strongly opposes. He regards the bone marrow changes as reparative and as a secondary result of the hæmolytic processes which his own observations have established. He points out that this classification of Ehrlichs, based on purely hæmatological considerations, simple and attractive as it is, breaks down in practice, since it groups together anemias of widely different clinical characters and of fundamentally different causation. One of the merits of Dr. Hunter's work is that he considers the anæmias from the etiological and clinical standpoint rather than from the purely hæmatological point of view like the Ehrlich school, though it may be objected with justice that in his book he hardly pays enough attention to the morphological characters of the blood as revealed by blood examination during life. In regard to his main thesis, it is difficult to resist the conclusions that the form of severe anæmia described by Addison is a well-defined and specific disease, and that it has to be differentiated from a group of septic anæmias with which it may be confused and with which it is not infrequently associated.

Having thus expressed our admiration for the character of his work and for the logical manner in which he has developed his views, we may be allowed to cavil at hisnomenclature. The title "severest anæmias" strikes us as a peculiar and somewhat inelegant one, as it is difficult to see the necessity for a superlative in nomenclature. Moreover, in regard to the term "Addisonian anæmia" we have always strenuously opposed the application of personal names to pathological conditions. The charts which are liberally distributed through the book are not always easy to interpret. and in the polemical parts of his work Dr. Hunter sometimes indulges in needless repetition, not to say reiteration. We have no other criticism to offer, and it should be added that he gives a bibliography at the end of the volume which should be of great value to workers at this subject, and which adds the utility of a highly important contribution to English medicine.

The Principles and Practice of Medicine. By WILLIAM OSLER, M.D. Oxon., F.R.S., F.R.C.P. Lond., Regius Professor of Medicine, University of Oxford. Seventh edition, thoroughly revised. London: Appleton and Co. 1909. Pp. 1143. Price 21s. net.

THE seventh edition of this well-known and excellent textbook has now been issued. The author remarks in his preface that the three years that have passed since the last edition appeared have been rich in additions to the knowledge of disease and its treatment, particularly in connexion with the acute infections. In this new edition all the more important advances have been incorporated—the epoch-making discoveries in syphilis, the work of the New York Pneumonia Commission, the triumph of the British army and navy surgeons in stamping out Malta fever, the splendid work of Gorgas and his colleagues at Panama, the studies of Strong and his associates in the Philippine Islands, the experiences of the last epidemics of cerebro-spinal fever in New York, Belfast, and Glasgow, and the all-important contributions on "carriers" in the acute infections which are likely to exert a marked influence on prophylactic medicine.

The section on parasites has been carefully revised and has received many additions. In the chapters on the diseases of special organs much new matter has been incorporated, including a new section on acute dilatation of the stomach, a complete revision of the subject of peptic ulcer in the light of recent surgical work, new sections on diverticulitis, parotitis, pancreatic and adrenal insufficiency, cedema of the lungs, Banti's disease, and polycythæmia. In the section on diseases of the nervous system the studies of Marie and his pupils upon aphasia, and the new work on spastic paraplegia, Oppenheim's disease, posterior meningitis, and other conditions have been added.

The earlier part of the section on lobar pneumonia has been rewritten. The remarks on the relation of trauma to this disease are interesting. Professor Osler states that pneumonia may follow directly upon injury, particularly of the chest, without necessarily any lesion of the lung. Stern's observations on this subject are quoted. This observer described three clinical varieties: first, the ordinary lobar pneumonia following a contusion of the chest wall; secondly, atypical cases, with slight fever and not very characteristic physical signs; and thirdly, cases with the physical signs and features of broncho-pneumonia. The paragraphs dealing with the history, etiology, modes of infection, and predisposing causes of diphtheria have been rewritten, and among other important additions the presence of the Klebs-Löffler bacillus in non-membranous angina and in healthy throats is duly discussed.

The remarks on the modes of infection of pulmonary tuberculosis have been recast. Infection by means of the intestines receives the attention required by such an important subject. The researches of Behring, Ravenel, and others are quoted, which dispose of the objection raised by Koch that if infection through the milk of tuberculous cattle were common, primary intestinal tuberculosis should be more frequent. Recent experiments, however, have shown in a striking manner that the lungs act as filters for particles absorbed from the intestines, and the investigations mentioned above have demonstrated that pulmonary tuberculosis can be produced in animals by feeding experiments, although the intestinal surface itself might remain intact.

In discussing the etiology of hypertrophic emphysema Freund's theory is mentioned; this observer maintains that a primary disease of the costal cartilages—a chronic hyperplasis with premature ossification—can bring about gradually a state of rigid dilatation of the chest, to which emphysema is secondary. Recent observations make it probable that there is a group of cases in which such changes occur in

young persons, particularly in the cartilages of the first three ribs.

It will thus be seen that this edition of Professor Osler's text-book has been brought fully up to date. It forms one of the best books for students preparing for their final examinations, and also a valuable work of reference for practitioners.

Southall's Organic Materia Medica. By JOHN BARCLAY, B.Sc., F.C.S. Revised and enlarged by ERNEST W. MANN. Seventh edition. London: J. & A. Churchill. 1909. Pp. 376. Price 7s. 6d. net.

WHEN a book has reached a seventh edition the task of the reviewer is comparatively light; it is obvious that the original intent of the author has been duly appreciated, that the work has found its public, and that the time for detailed criticism has long been passed. But for these considerations there might be a strong temptation to investigate seriously how far this book, which we learn from the title page is designed for the use of teachers, pharmaceutical and medical students, chemists, druggists, and others, was likely to be of any particular service to any of these classes. To educate the teacher is at all times a praiseworthy object, but to place this book in the hands of the average medical student might cause some dismay, since the arrangement of material entails the separation of much that might be more conveniently grouped together. Thus by dealing separately with all seeds, roots, leaves, flowers, &c., there is troublesome repetition of many considerations connected with composition and uses, which do not depend upon the part of the plant employed. It might also be suggested that at the present time there is but scant advantage in a classification based upon the special part of plants employed in medicine, since, for example, there is no resemblance in the chemical composition, the uses, or the preparations of the different roots, woods, or leaves. In fact, this system of classification seems to be a survival from the days when examination questions favoured cram rather than intelligence. But as a compilation dealing with the more important animal and vegetable drugs employed in medicine this work will probably be useful as a book of reference; it avowedly includes almost verbatim official descriptions taken from the British, United States, and Indian Pharmacopæias, and the work of condensation has been effected judiciously. There is an admirable index, and the different type employed facilitates ready reference. The limitation to animal and vegetable drugs must be remembered; the term "organic" is not employed in a chemical sense; synthetic carbon compounds are not included in the scope of this work.

A Study of the Bacteriology of Drinking Water-supplies in Tropical Climates. By Major WM. WESLEY CLEMESHA, M.D. Vict., D.P.H., I.M.S., Acting Sanitary Commissioner for Madras. Assisted by Assistant-Surgeon I. SEETHAPATHY AIYAR, L.M. & S., Senior Laboratory Assistant, King Institute, Guindy; and V. Govindarajn Mudaliyar, B.A., Junior Laboratory Assistant, King Institute, Guindy. Madras: Government Press. 1909. Pp. 346. Not for sale.

ANYONE who has had anything to do with the bacteriology of water in India knows well that outside the special water-supplies of cantonments most of the waters which are used, more especially by the rural population, are loaded with fescal contamination from either man, cattle, or goats. It is hardly credible that natives are so backward in their knowledge of sanitation as to raise no objection to throwing cholera corpses into the only available water-supply of a large village. Frightful epidemics of cholera occur amongst the natives at times, and dysentery is always present to some extent. When we consider the foul water drunk by most

natives we cannot but wonder that the mortality from water-spread diseases is not higher. This circumstance is well brought out by Major Wesley Clemesha in this study of the bacteriology of the drinking water-supplies in tropical countries. Of no less than 18 towns in Madras that are all provided with a protected supply the water on analysis was so bad that no medical officer of health in Europe would pass it as fit for human consumption, and yet a reference to the health statistics of these towns shows that the people (natives) are distinctly favoured as compared with those in rural areas, and that their health is, broadly speaking, satisfactory. There has been little or no detailed research on the bacteriological question as it affects water-supplies in India, and up to the present date the various workers who have made bacteriological examinations have either accepted the European standards as applicable, or have individually modified them to suit what they considered to be local requirements. The method adopted by Major Clemesha is a modification of one described by Dr. A. MacConkey in his work on lactose fermenters 1 and in subsequent papers. It may be briefly stated that by using saccharose and dulcit he divides all lactose-fermenting organisms into four groups and by further fermentations and other tests the individual species are studied separately. In time we may be able to assign a relative value, as an indicator of pollution, to each of these different organisms, and it is hoped by Major Clemesha that the publication of his work will induce officers in other parts of India to carry out their water analyses on these lines, so that comparable results may be obtained. He gives detailed accounts of the methods adopted as a standard in his laboratory at the King Institute,

In Chapter VIII. the effects of tropical sunlight on fæcal organisms in water are well discussed, and the results of a large series of experiments are described in detail, the following general conclusions being arrived at: (1) That the sun has a very powerful action in destroying all fæcal organisms in water, particularly when they are "naked" and not surrounded by mucus derived from the intestine; (2) that all fæcal organisms do not possess the power of resisting the action of sunlight to an equal degree; (3) that it is possible to divide feecal organisms with a reasonable degree of accuracy into groups according to their resistance to sunlight; and (4) that as the action of the sun is more powerful in destroying the fæcal organisms on the surface layers of a large volume of water, it is more practical for the outlet from a reservoir to be near the surface than from the lower lavers.

The relationship of cholera to water-supplies is discussed in Chapter XV. It is noted that the bare cholera figures in any report are not of great value unless certain facts as to the origin of the disease are explained. Thus, although it is true that cholera is spread chiefly by a polluted water. there is no doubt whatever that other methods of transmitting the disease do exist; cholera, for instance, like enteric fever may be disseminated by flies or imported. The principal factor in importation into stations in India are the numbers of pilgrims, beggars, and mendicants who visit the temples in certain districts. The index of purity of any given water-supply of a locality can, however, be roughly gauged from the following returns: (a) presence or absence of cholera; (b) the prevalence of diarrhæa and dysentery in children under five years of age; and (c) the presence of dysentery and diarrhose in the community as a whole.

Part II. of the work gives separate analyses of the

various water-supplies of towns in the Madras Presidency divided into three groups: (1) those towns supplied by water derived from rivers; (2) those derived from impounded surface waters; and (3) those derived from wells or springs. The whole bears evidence of careful laboratory research carried out under the unfavourable climatic conditions of Southern India, and these have only to be experienced by any worker to be appreciated.

LIBRARY TABLE.

The Health of the Nations. (Compiled from Special Reports of the National Councils of Women.) Aberdeen: Rosemount Press. 1909. Pp. 191. Price 1s.—The excellent work parformed by the International Council of Women during its comparatively short existence of 29 years has been of benefit not only to the women of the 22 nations affiliated in the International Council but also to the community at large. In no respect will their influence be more useful to the nation as a whole, as well as to women, than in their recent work in connexion with public health. At the request of the President, the Countess of Aberdeen, the International Council of Women has, during the quinquennial period 1904 to 1909, prepared reports of matters concerning the public health in the respective countries. The Countess of Aberdeen set the lines upon which the reports should be drawn up, desiring special reference to (1) care of infants and children; (2) housing of the people; (3) conditions under which working women carry out their work; and (4) measures in force against tuberculous disease. The practical work done for the prevention of tuberculosis by the Countess of Aberdeen during her residence in Ireland is of course well known to our readers. The health reports submitted by the various national councils have been compiled by the corresponding secretary, Mrs. Maria Ogilvie Gordon, D.So., Ph.D., and are now obtainable in book form for 1s. The reports from the 18 countries form most interesting reading, and have been arranged for easy reference, Mrs. Gordon having translated or condensed where she deemed it advisable to do so. The book also contains the address delivered by the Countess of Aberdeen at the last meeting of the International Council of Women held at Geneva in 1908; and Mrs. Gordon has written a concise and descriptive account of the formation and growth of the International Council of Women, which completes a most interesting record.

Lehrbuch der Magenkrankheiten für Aerzte und Studierende. (Text-book of Diseases of the Stomach for Practitioners and Students.) By Dr. HANS ELSNER. Berlin: S. Karger. 1909. Pp. 490. Price M.12.—The author tells us in the preface that his book is intended to take a middle place between detailed systematic treatises on gastric diseases and short practical text-books. On the whole it resembles the former rather than the latter. It is divided into a general and a special section, the former extending to 200 pages. In this a full account is given of the methods of examination which are employed in disorders of the stomach, including the chemical tests which are given at considerable length. In the second part the order of sections is: gastritis, achylia gastrica, superacidity, gastric ulcer, erosions, hypersecretion, cancer, disorders of motility and dilatation, gastroptosis, nervous dyspepsia, and, finally, a small group of functional defects. The opinions expressed are, on the whole, conservative and not very novel. No allusion is made to the view which is coming into prominence in this country as to the unreality of many of the cases of gastric ulceration diagnosed in women, even when hæmoptysis is present. In the treatment of cancer Dr. Elsner believes that there is no future before extensive operations, such as

¹ Journal of Hygiene, July, 1905.

total and subtotal gastrectomy. Pylorectomy he admits as useful, and likely to prove still more beneficial in the future. The book is well got up and adequately illustrated, and is written in an agreeable style. It is a useful and readable exposition of sound medical teaching in the field with which it deals.

Notes on Dental Anatomy. By G. A. PEAKE. London: Claudius Ash, Sons, and Co. 1908. Pp. 104.—These are the notes of Mr. Peake's lectures, and they contain an enormous mass of information about the teeth. The highly condensed information is generally sound, except that the author's ideas of the development of the jaws are a little archaic, and it is perhaps unwise to call the newt and frog reptiles as he does on p. 26. Mr. Peake says that the notes have been published at the request of dental students, but we doubt the wisdom of granting the request. Students are much too fond of "potted knowledge," and few can retain it beyond the date of an examination. A book twice as long, containing half the facts, would have been more valuable.

Ueber das Verhalten hämolytischer Serumstoffe beim gerunden und kranken Kind. (On the Quantities of Hæmolytic Substances contained in the Serum of Children in Health and Disease.) By Dr. ERNST MORO, Privat-docent and Oberarzt in the Children's Clinic of the University at Munich. Wiesbaden: J. F. Bergmann. 1908. Pp. 100. Price 3s.—It is well known that the process of hemolysis n an immunised animal is carried out by two separate substances—the immune body (amboceptor or copula) and the complement. Dr. Moro endeavoured to ascertain the amounts of each of these substances in the blood of children. He found that in new-born infants the immune body by which foreign blood corpuscles are attacked is present only in small amount, and that there is also a smaller quantity of the complement than in adults, the actual amount varying in different individuals at all ages. The most interesting part of the pamphlet is, however, the comparison of the amounts of complement present in the serum of different classes of atrophic children. The author found that in infants who suffered from atrophy due to inability to assimilate artificial food the amount of complement was very small, whereas in others suffering from alimentary intoxication the amount was actually increased, as in infective diseases. Injection of normal saline solution leads to an increased formation of complement in patients who have good powers of resistance. The failure of this increase seems to be a sign of bad prognosis, and may perhaps prove to be a test possessing some clinical value. Further studie are in progress as to variations in the amount of immune body present in different diseases.

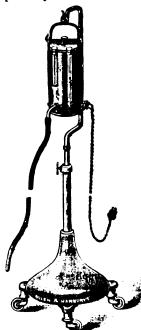

Invalid Cookery: a Handbook of Cookery for the Sick Room, By Miss PEARSON and Mrs. BYRDE. London: W. Thacker and Co.; Calcutta: Thacker, Spink, and Co. 1909. Pp. 39. Price 1 rupee. 1s. 6d.—Take it all round this is an excellent little book. We are particularly pleased to note the sensible remarks about water for the sick with which Part 1 opens. Even in these modern days every medical man will bear witness to the widespread delusion that cold water is harmful for a sick person, and Miss Pearson and Mrs. Byrde have done well to point out that water is most beneficial. In the recipe for barley water, too, they have done right to mention the fact that the expression "barley water" means at least three different kinds of fluid. We notice that in the recipe for white wine whey the authors are led into looseness of expression, for they say that "all the solids of the milk are removed in the curd." This, of course, is incorrect, for the whey contains salts and sugar. This error should be corrected in a future edition. The recipes for

convalescent cookery are for the most part admirable, but we do not think that the directions given for making an omelette on p. 36 would result in the production of a really good omelette. One dessertspoonful of butter would not be enough for two eggs, and the stirring about in the pan would result in a mixture much more like buttered eggs than an omelette. But the art of making an omelette is not to be learned from a book; to describe the proper method of cooking one is almost impossible in writing, a practical illustration is always wanted.

Hew Inbentions.

AN APPARATUS FOR CONTINUOUS PROCTOCLYSIS.

The plan of continuous administration of warm saline solution by the rectum, introduced by Dr. J. B. Murphy of Chicago is in my opinion one of the greatest advances in abdominal surgery which have been made within recent years. Its routine adoption leads, I believe, to more rapid, and certainly to more comfortable, convalescence after cueliotomy, and its beneficial effects in cases of general septic peritonitis would have surprised me had I not been prepared for them by hearing from Dr. Murphy's own lips of the wonderful results which he has obtained in the treatment of this serious condition since the adoption of the practice of continuous proctoclysis. Success in using the Murphy method depends

on attention to detail, and the two most important points are: first, the regulation of the flow from the supply-can by gravity alone, and not by constriction of the delivery tube; and, secondly, the maintenance of the saline at a constant and appropriate temperature. To obviate the latter difficulty I have had an apparatus made which does away with the necessity for constant supervision. The apparatus consists of an electro-plated douche can which holds about five pints. In the front of the can are a thermometer and a gauge glass, by the side of which the can is graduated in half pints, so that the amount of saline entering the rectum can be readily estimated. The saline leaves the can through a delivery tube with a half inch bore, to which is attached three feet of rubber tubing connected with a large rectal tube. Under

the bottom of the can is an electric heater, which can be connected with any electric supply of suitable voltage by means of a flexible cord and wall plug. The can is suspended on an adjustable stand, mounted on castors, so that it can be readily wheeled up to the bedside. I have found by experiment that with a ward temperature of from 65° to 70° F. the solution in the can must be kept at a uniform temperature of 106° in order to insure that the saline enters the rectum at a temperature of from 99° to 100°. The electric heater is so made that if the saline solution is put into the can at a temperature of 106° the temperature remains almost constant so long as the current is switched on.

The apparatus, which has been made for me by Messrs. Allen and Hanburys, answers its purpose admirably and can be left for several hours without any attention.

THE LANCET.

LUNDON: SATURDAY, OCTOBER 9, 1909.

The Enzyme Treatment of Cancer.1

HAD the enzyme treatment of cancer been able to achieve any of the exploits attributed to it we should expect that the outpourings in the press on both sides of the Atlantic about three years ago would be by now finding justification in the publication of properly authenticated therapeutical triumphs. But all that has followed justifies both the scepticism originally accorded to the statements of the rival discoverers of the treatment and the verdict which quickly followed, that trypsin, whether exhibited with or without amylopsin, is not a cure for cancer. The lapse of time has shifted the attention of those interesting themselves in the alleged relation of ferments to cancer from "trypsin" to "antitrypsin," through the agency of which attempts are being made to obtain a quicker or more certain diagnosis of the presence of the disease; but unfortunately the anticipations aroused by the earlier positive statements of the diagnostic value of what has been styled the "antitryptic" index have been damped by the establishment of the fact that an increase in the power of the serum to neutralise the activity of trypsin is not specific to cancer, but common to many infective diseases, the phenomenon being explained as coincident with the disintegration of leucocytes and liberation of their contents. It would appear that in the history of cancer the chapter on the vogue of the ferments and antiferments will be an exposition of the danger of hastily applying in practical medicine the nebulous notions born of imperfectly assimilated knowledge. Less is known about the inhibition of ferment action than about ferment action itself, and the flight of the enthusiasts from the realm of the ferments to the realm of the anti-ferments appears to be a portent that of all things caution is needed in appraising the value of any positive statements which may be made with regard to the bearing of this line of inquiry either on the treatment or the diagnosis of cancer.

We do not ignore the activity centring round ferments and anti-ferments in their supposed bearings upon cancer; rather would we emphasise the seriousness with which all investigations of the kind should be undertaken, and the need for their conduct or control by persons properly equipped for a most difficult study, beset with more than the average number of pitfalls. Once a positive statement finds currency of the value of any alleged remedy it is difficult or impossible to banish it from practical therapeutics. The patient will insist upon trying it in spite of the protests of the medical attendant. Thus trypsin has come to take a

place in the already too lengthy list of alleged cures for cancer. Although it is as useless as any other reputed substitute for surgical treatment, it may hardly be dislodged from its place in the lay mind until the progress of investigation reveals to the physician and surgeon rational substitutes for, or adjuvants to, operation. With regard to such alleged remedies it is essential, however, that the medical profession should have clear and sound views as to why they have been condemned as useless. The possession of this knowledge and of the convictions based upon it, on the part of those who may be importuned to employ such remedies, is of as great importance to the practitioner himself as it is to his patients. For this reason we have only the highest praise for a painstaking and elaborate report on the systematic submission of 100 cases of cancer to "the enzyme treatment of cancer" during the past three years in the New York Skin and Cancer Hospital. Undeterred by the discredit into which the methods of some of its exponents had brought the theory, Dr. WM. SEAMAN BAINBRIDGE, the author of this report, has fulfilled his undertaking to give the treatment a fair trial, both in operable and in inoperable cases. Many of the patients have been followed to their homes, and nurses provided, after leaving hospital, while everything possible has been done to make the clinical and pathological observations complete. The list of patients and the account of the results given by Dr. BAINBRIDGE are records of the miserable failure of the treatment; but they are monuments of industry which will be of service in the interests of sufferers from cancer. We recommend the perusal of this report to all who may have to inform themselves of the value of the treatment of cancer by trypsin and amylopsia.

We would point out as a proof of the straightforward character of the enquiry that throughout touch seems to have been kept with Dr. J. BEARD, whose views were more particularly being put to the test, and everything was done to meet the requirements of the modifications he suggested in the treatment. Of general interest is the fact that the injection of the most powerful solutions of trypsin is not followed by toxic symptoms assignable to the products of digestion of tissues. As much as 100 minims of the strong solution (special quadruple x) could be given for days without untoward effects. Dr. BAINBRIDGE adds: "From this it will be seen how absurd were some of the earlier claims of 'cares' as well as the strange symptoms and 'terrific' results from the small doses employed." The amelioration of symptoms was in some cases as effectively induced by the injection of sterilised distilled water. No wonder the report concludes that trypsin does not check the cancer process, does not prevent metastases-in short, does not cure cancer. The negative result of the investigation is to be regretted, but the courageous persistence in its conduct in the face of discouragement, and the care with which the tests have been carried out in all particulars by Dr. BAINBRIDGE for the New York Skin and Cancer Hospital, may serve as a model to other institutions. A negative result of this kind has the great value we have indicated, in that the medical profession have before them chapter and verse for their placing no faith in trypsin and none in persons who persist in advocating its use by repeating stories of alleged "ource"

¹ Scientific Report on Investigations with reference to the Treatment of Cancer, No. I., New York, 1909.

when, as a matter of fact, the patients referred to have been proved to have died from the disease. Trypsin has no selective action for cancerous tissue. If when injected into the tissues it is liable to bore its way into a large vessel, thereby causing immediate death from hæmorrhage, it is not a substance which should be lightly administered, even when called for by the sufferer.

The Red Cross Ambulance Scheme for the Territorial Army.

A SCHEME for the organisation of voluntary aid in connexion with the military medical service of this country in case of invasion has recently been issued by the War Office. The principal points were summarised in THE LANCET of August 21st, p. 569. We apprehend that this scheme will be welcomed by all members of our profession who are animated by a real spirit of patriotism—that is, we hope, by every one of us-by all who feel that it is not the duty of a special class of persons only to take their part in the defence of the kingdom, but that everyone without exception, who is in a state of physical fitness, should do what in him lies to safeguard "this blessed plot, this earth, this realm, this England," from attack. We can well believe that all the medical men who served in the Volunteers of a few years back, in whatever capacity, were actuated by such feelings, for there was certainly little inducement of any material kind for our profession to serve in that force, either with the Volunteer battalions of line regiments or with those select and scanty bodies, the Royal Army Medical Corps Militia, or Volunteers, on whom no sunshine of official favour ever shone. The contrast between the old order of things and the recently issued comprehensive scheme of organisation is most marked. We now have a well-designed system, under which any medical man who is sound in wind and limb may find a position ready to his hand, in which he can render service to his country without any serious inroad on his own professional duties or well-earned leisure.

In this scheme it is taken for granted that there will be need for voluntary aid for the sick and wounded in the event of warlike operations being conducted within our shores, and that this necessity is now fully recognised by the public; it is also acknowledged that there is a tendency on the part of societies formed for the purpose of providing this aid (as for most purposes, benevolent or otherwise) to act independently of one another—that is, to overlap and interfere with each other's work; and it is laid down that "efficiency cannot be attained unless all voluntary aid be coördinated." The scheme, accordingly, is formulated on this main principle, drawing some of its details from the Red Cross Society of Japan and the Voluntary Aid Companies in Germany, and is therefore to some extent the outcome of practical experience that has been already obtained The county system of organisation (being the system upon which the Territorial Force is organised) has been adopted. The county associations and the local branches of the British Red Cross Society will provide the "voluntary aid detachments," the duties of which will be to make use of local resources for improvising accommodation and for, so that by relieving each other the private practice of

transport of wounded, and for arranging for their temporary care and treatment until they reach the general hospitals. In the medical organisation of the regular army, the "Expeditionary Force," provision is, of course, made for care of the sick and wounded in the field by a regimental medical service, and in hospital by an establishment of "stationary" and "general" hospitals. The sick and wounded are conveyed from the field to the hospitals at the base or on line of communications by field ambulances and by a special mobile unit, the "clearing hospital," which receives and cares for them until they can be conveyed to the regular hospitals, by whatever means of transport-road, rail, or water-that is available. In the organisation of the Territorial Force, however, no personnel for the "clearing hospitals" is provided; nor is there any provision of personnel for the "stationary" hospitalstemporary hospitals, that is, along routes of evacuation; nor have buildings been chosen fitted for use as "general hospitals," This incompleteness in the scheme was intentional, as it was considered that in these particular departments of medical administration a suitable field exists for the employment of voluntary aid; and, in fact, that "it was eminently to be desired that every opportunity should be given to the British Red Cross and other societies of taking a share in the work appropriate to those who in all civilised countries seek to mitigate the lot of the sick and wounded in war." As everyone is aware, there always has been a very keen desire on the part of the public to alleviate the sufferings of the troops during campaign operations; it is also known to very many that, for one cause or another, the large sums of money subscribed have not infrequently been to a great extent wasted through want of coördination between the official military and the philanthropic lay administrators. The new organisation now comes in to provide this coordination that has been so deplorably absent in the past. The County Association is charged with the responsibility of the organisation of voluntary aid in this country by the formation of "voluntary aid detachments" through local branches of the British Red Cross Society, each county group of these detachments being under the command of a county director. The training of these detachments will be directed towards the work to be done and will include such things as improvisation of stretchers, preparation of country carts for reception of wounded, conversion of farmhouses, public buildings, and, possibly, whole villages or small towns into temporary hospitals, organisation of evacuating stations, arrangements for transport of sick and wounded, and provision of the material and personnel required. It is obvious that for any degree of efficiency to be attained in such an organisation a great deal of work is necessary on the part of the voluntary aid detachments that are to be formed. We believe, however, that there is sufficient patriotic spirit in the medical and nursing professions to provide the required number of physicians, surgeons, and nurses; moreover, it is to be acknowledged that the authorities have shown a real desire to make the conditions of service as little onerous as possible. Thus, each battalion of the Territorial Force has two medical officers attached to it: one is all that is needed to do the work, but two are allowed

each may be interfered with as little as possible. Again, as the ordinary work of a civilian hospital is very similar to that of a military general hospital, it is not intended to call up the medical and nursing staffs for duty in peace time; and the number of these staffs enrolled is much in excess of mobilisation requirements, so as to cause the minimum of interference with the ordinary routine duties of each. This shows a reasonable attitude on the part of the military authorities and an absence of red tape that deserves the fullest recognition.

The scheme for the organisation of voluntary aid in connexion with the military medical service of this country is so extensive and complex that it is almost impossible for anyone, not actually engaged in military medical administration, fully to realise the necessity or otherwise of the several items that go to make up the whole. The county associations are to be prepared to have their general hospitals fully equipped and ready to receive patients in one week from the date of mobilisation. The minimum equipment required is comprised in 45 schedules, extending over 25 foolscap pages, all but two having double columns; the total number of separate items amounts to about 3000. It seems hardly hypercritical to suggest that such an elaboration of detail is unnecessary, and that in a time of national emergency, when England is actually invaded, such things as pepper-casters (Schedule 1), backgammon boards (Schedules 6 and 10), soup tureens (Schedule 18), and art serge window curtains (Schedule 29) might surely be dispensed with. Of the scheme generally, as far as we are able to judge from our own standpoint, we feel bound to express hearty approval; and we commend it to the profession throughout the country as a comprehensive, workmanlike, and feasible scheme of organisation of voluntary medical aid in time of national emergency, which should meet with a ready response from every patriotic member of our profession-Some labour and time must be given, some deduction made from the leisure or recreation, scanty enough as these are already for most of us in actual practice. But the arrangements appear to have been designed expressly to make no greater demands on those who respond to the call of the national need than are absolutely necessary, and this reasonable spirit will, we believe, be met by a like spirit of sober, determined, self-sacrificing patriotism on the part of all ranks and branches of the medical profession.

"Nurture or Nature."

UNDER the very suggestive title of "The Relative Strength of Nurture and Nature," a lecture by Miss ETHEL M. ELDERTON, Galton Research Scholar, on the respective operations of these two forces in promoting or restraining the development of children, has just been published in the Eugenics Laboratory Series of the University of London, and furnishes a convenient illustration of the work which is being conducted in the Galton Laboratory, and of its probable practical value in assisting us to deal with some of the pressing problems of to-day. The object of Miss Elderton's inquiry was to ascertain whether the unsatisfactory conditions

of physical strength and of intelligence displayed by a large proportion of what may be called "slum children" are mainly due to their surroundings or to their parentage; and she commences her discourse by some apt illustrations of the highly complex character of the problem, and of the difficulty of discovering the originating factor. An analogous difficulty, indeed, was stated many years ago by the author of the delightful little apologue entitled "The Cat's Pilgrimage," a story which relates how a domesticated pussy, tired of luxurious surroundings, went forth to investigate for herself the larger world around her. She lost herself in a wood, was desperately tired and hungry, and night was coming on. No saucer of milk could be discovered in any direction, but presently she saw an owl sitting on a bough, and she appealed to the bird of Minerva for aid and consolation. The owl advised her to seek refuge in philosophy, and declared that she herself was at the very time finding consolation under trouble in meditating upon the problem "Which came first, the owl or the egg?" Pussy objected that the problem was necessarily insoluble, but was promptly answered that therein lay its principal advantage. Miss Elderton points out that we might discover that the mentally and physically fitter child comes from the cleaner and less crowded home, and might therefore argue that the spread of such homes is a "condition for national progress." But further investigation might show that the essential condition for such homes is the existence of mentally and physically fit parents, and that the fitness of the children flows after all from the parentage and not from the home. Or, if we took the problem of the employment of mothers, we might discover that employed mothers had the healthier children, and on this ground might oppose attempts to restrict the factory work of women during childbearing years. But on further investigation we might find that such mothers were, on the whole, older and with older children, from whom time had weeded the weaklings. Or we might find the death-rate of innkeepers to be much in excess of that of the clergy, and might overlook the fact that the average age at starting the occupation of innkeeper is higher than that of entering the Church, because to keep an inn is the ambition of many men who begin life in other callings. Or we might inquire into the effect of the drinking of the father on the health and ability of the offspring. We might find that the drinking father had better developed children than the non-drinker; but this might be because the drinker was the better workman, and the superiority of the children an inheritance, or that he earned better wages, and thus, in spite of drink, that his children were better fed. In other words, "Which came first, the owl or the egg?"

Miss Elderton describes the enormous part played by environment in modifying living forms as being of two kinds: a change in the somatic characters following upon the transfer of the individual to different surroundings, or his treatment under different conditions of nurture; or a change in the germ characters of the race, owing to the environment selecting for survival a certain differential class of individuals, and their somatic characters thus becoming more frequent and possibly dominant in the population owing to the strength of heredity. It is with the former description

¹ Dulau & Co., 37, Soho-square, W. 1909. Pp. 40. Price 1s.

of influence that her inquiry was concerned, and it has been conducted by an endeavour to establish the "coefficient of correlation" between certain characteristics of parents and offspring. It is said to have been ascertained, by "a variety of investigations," that the correlation between physical and mental characters in parent and offspring is about 0.45 to 0.50; and the question appears to be whether this relation is appreciably modified by what may be described as accidental causes, such as are comprised within the general term "nurture." Miss ELDERTON shows that it might be easy to attribute to environment a condition which was really a secondary influence of heredity. A weakling may follow an unhealthy trade because he has not strength for a better one; and his offspring may be physically inferior because he is a weakling, and not because he follows an unhealthy trade. endeavouring to find her way out of the various difficulties with which the questions before her are beset, Miss ELDERTON has been able to avail herself of a report upon 1400 school children of the city of Edinburgh, a record of measurements of 72,857 children attending the public schools in Glasgow, and an account of the children in the "special" schools in Manchester. In all these reports some information was given about the home circumstances of the children concerned, and, among other points, about the "drinking," the health, and the physique of the parents; but it seems reasonable to suppose that much of this information might be quite as likely to mislead as to instruct, and it is at least certain that the word "drinking" would be employed in different senses by different observers. The inquiry, as a whole, appears to show that the influence of Nurture is small when compared with that of Nature, that the physically and mentally weaker stocks are reproducing themselves at a greater rate than those of sounder physique and intelligence, and that modern attempts to improve the environment of the children of these weaker stocks are not likely to be followed by any material improvement either in such children or in their descendants. So far as can be seen at present, it appears that improvement in social conditions will not compensate for a bad hereditary influence; and that the problem of physical and mental degeneration cannot be solved by preventing mothers from working, by closing public-houses, or by erecting model dwellings. "The only way to keep a nation strong is to see that each new generation is derived chiefly from the fitter members of the generation before."

The general conclusions at which Miss Elderton has arrived are very strongly supported, on somewhat different grounds, by Professor Karl Pearson, in a lecture appearing in the same series, in which he endeavours to trace the falling birth-rate of Great Britain to what may generally be described as "factory legislation," and to the impediments which that legislation has thrown in the way of employing children as wage-earners, contributing in an important degree to the maintenance of the families of which they form part. He says, in effect, that the child, who was once a helper at a comparatively early age, is now nothing but a burden until that age is long past, and that the more prudent of potential parents decline to take him upon

their shoulders, leaving the business of continuing the race to the comparatively shiftless and unthrifty. He urges that the only way to check the consequent degeneration is by legislation which shall encourage child-bearing among the classes who now avoid it, and indicates certain methods by which this end might be attained, methods such as relief from taxation as a reward of parentage, educational endowments, a modification in favour of respectable parents of the system of old-age pensions, and various other departures from the methods by which "unthinking philanthropy has crippled our power of modifying race fitness." Taken together, the two lectures form a powerful appeal to the more reasoning portions of the community against the practices of the more impulsive, whether these be actuated by ignorant benevolence or by equally ignorant striving after vote-catching, and they at least serve to show the absolute necessity of knowledge as a prelude to useful activity. The custom of "acting foolishly but meaning well" is of far greater antiquity than the poet who denounced it, and we fear it is likely to continue, notwithstanding the excellent work of the Galton Laboratory, for many generations to come. In the meanwhile that work will, we think, commend itself to the judgment of the medical profession, and might be made more generally known than it is at present by a very moderate degree of exertion on the part of medical practitioners. We cannot but add that any endeavours which might be made in this direction would be greatly aided by the adoption of a more lucid and less technical style on the part of those by whom the researches of the laboratory are set forth. To those who would persuade or convince a mastery of the resources of language is as essential as the mastery of his foil is to a fencer; and as long as the examples of FARADAY, of TYNDALL, of HUXLEY, of DARWIN are remembered there can be no excuse in any literature intended for the public for either clothing the teachings of science in abstruce technicalities or for veiling their essential attractiveness. beneath obscurities either of construction or of diction.

Annotations.

"Ne quid nimis."

MEDICAL FEES IN CONNEXION WITH THE CIVIL SERVICE SUPERANNUATION ACT.

GOVERNMENT departments are never liberal in remunerating medical practitioners whose services have been required in some capacity or other, and they have even been known to ignore the question of fees when specifying circumstances under which medical advice must be promptly obtained. The time-honoured maxim that a labourer is worthy of his hire is as true in the present day as in any previous period. Gratuitous advice, however, is constantly being given by practitioners in the cause of charity as well as in attendance on impecunious patients, but this kind of altruism is not free from the risk of encouraging the public to under-estimate the money value of professional service. The question of medical certificates and health reports stands somewhat apart from that of medical attendance. They are frequently in request, they may be troublesome to prepare, they may involve some responsibility, and they may have to be given either gratis or for a very moderate consideration. This is particularly

the case with certain certificates which are to be granted in connexion with the Civil Service Superannuation Act, 1909. Hwery male civil servant over 55 years of age who desizes to be brought under the provisions of the Act must ebtain a medical certificate setting forth certain particulars in a prescribed form. It is understood that where civil servants are in receipt of salaries of less than £150 a year and are entitled to free medical attendance, arrangements have been made by the Government for the certificates to be supplied by the official medical officer, but in the case of officers not entitled to free medical attendance the certificates of any fully qualified medical man will be accepted and a sum of 5s. towards the expense of procuring it will be allowed from the public funds. The members of the Civil Service who benefit under the Act receive annual amounts calculated on the basis of (1) their annual salaries and other emoluments, and (2) their length of service. In the case of those whose position does not entitle them to free medical attendance the effect of the Act is to provide them with what is virtually a new insurance, varying in value from about £170 to many hundred pounds, and it will at once be seen that a fee of 5s. for the requisite medical examination is far below the scale of fees universally paid by the insurance companies. It is, therefore, to be hoped that medical men will not allow themselves to be misled into accepting fees which do not accord with the standard of payment for such valuable insurance work at the present time. Fees ranging from 10s. 6d. to 21s. cannot be considered excessive for making these medical examinations and for granting the certificates.

THE USE OF ELECTROLYTIC FLUID IN SWIMMING BATHS.

An interesting report has recently been presented to the baths and washhouses committee of the metropolitan borough of Poplar by the medical officer of health, Mr. Frederick W. Alexander, in which the evidence appears to be decidedly in favour of the advantages gained by treating the water in swimming baths with electrolytic fluid. The fluid is obtained by the electrolysis under certain conditions of a solution containing magnesium chloride. the result being a solution of magnesium hypochlorite which serves as an efficient deodorant, oxidiser, and disinfectant. The fluid is made by the council's officers for purposes of general disinfection. The first experiments tried were made with the dirty used water in the baths before it was run off into the sewers. For financial reasons, as we have before pointed out, water in public swimming baths cannot frequently be changed, and after a number of people have bathed in the same water, more especially in baths used by persons who have no washing bath accommodation in their own homes, the water must become contaminated with organic matter and, of course, with bacteria. Further, it must be admitted that swimming-baths may be used by persons who are unconsciously or otherwise suffering from communicable disease. There are, in fact, several obviously easy ways by which bath water can seriously be polluted. Mr. Alexander says that changes are noticeable in the water after it has been 24 hours in the baths; it assumes a darkish colour, and if left in the baths grows still darker. At the bottom of the bath a alime tends to form and the bather experiences a feeling of stickiness about his body. In one of the experiments carried out with the dirty used water an excessive amount of electrolytic fluid was purposely added. The water was previously wery dark in colour and the bottom of the bath was obscured. A preliminary test on a small scale showed that one gallon of the electrolytic fluid added to 1000 gallons of the dirty water would just exidise the

organic matter present. Dirty water to which three tis this quantity of electrolytic fluid was added showed after two bours that the organic matter had been exidised, while there was still present an excess of electrolysed fluid. To the bathers, it is stated, there was no evidence that an addition of the fluid had been made so far as feeling was concerned, and the taste of the water was not peculiar. In appearance the water gave distinct signs of having cleared itself, it had lost its dirty, dark-brown colour, and "looked like ordinary sea-water." Chemical examination proved the absence of oxidisable matters, while bacteriological examination showed that after incubation for four days no organisms were found growing in the cultures. The cost of treatment is small, 80,000 gallons of the electrolytic fluid having been produced at the borough electrolytic plant installation during a period of four years, at a cost for electricity and materials of under £160. There can be no doubt that if public swimming-baths can be treated at intervals by this simple, economical, and scientifically cleansing method, and if public experience is able to show that the water so treated is without injurious action on the body of the bather, a very valuable advance has been made in an important branch of public health administration, especially in poor crowded localities.

THE BRAIN OF THE LATE PROFESSOR MENDELÉEFF.

Professor W. von Bechterew and Professor R. Weinberg have made a very complete study of the brain of Professor Mendeléeff, so widely celebrated as a chemist, and issued their account, with excellent illustrations, as the first of a series of anatomical monographs which are to appear under the editorship of Professor W. Roux of Halle. Professor Mendeléeff, or Mendelejew, as his name appears in the German monograph, was a heavy, corpulent man, with long fair hair, blue eyes, ruddy skin, and a short, broad head, the width being 87 per cent. of the length. The outstanding feature of his mental life was his powers of visualisation; his concepts became vividly alive, mobile, and plastic; his vocabulary, although not overflowing, was ample and very apt. His brain was rather above the average in weight (1571 grammes) and the convolutions were comparatively simple in their arrangement. So little do we know of any correlationship between special mental gifts and the surface form of the brain that not even those who have made a special study of the brains of celebrities could have guessed that this particular brain belonged to one of the foremost investigators of his time. Professor Mendeléeff's brain shows three interesting features: (1) the left parietal region is extensive and highly convoluted; (2) the posterior parts of the frontal lobes in the neighbourhood of the second frontal convolution are more massive than usual; and (3) the temporal lobes are small and simple. The two features first named are probably correlated with Professor Mendeléeff's special gifts of visualisation and creative imagination; the third may be associated with his lack of musical appreciation. The authors do well to remind their readers that our knowledge of the genius-brain is still in its "baby shoes" (kindersohuhen). They do not share the despondent view of Professor Stieda, who is convinced that there is absolutely no correlationship between the surface form of the brain and the mental life of the individual, and that all attempts to solve the functions of the brain in this direction are futile. Progress of knowledge has always justified those

¹ Das Gehirn des Chemikers D. J. Mendelejew. Von Professor W. von Bechterew und Professor R. Weinberg. Anatomische und Hntwicklungsgeschichtliche Monographien herausgegeben von Professor W. Roux. Heft 1, pp. 22, eight plates and a portrait. Leipzig: Englemann, 1909. Price 7 marks.

who sought an explanation of form in function, and those who watch most closely the growth of our knowledge of the brain are most sanguine that the explanation of its form will be first found by the physiologist. Whatever the ultimate interpretation of the facts may be there can be no doubt that Professor Bechterew and Professor Weinberg have done a real service in placing on record an account of the brain of the greatest of Russian chemists.

THE INVESTIGATION OF BERI-BERI IN THE FEDERATED MALAY STATES.

MANY investigations into the causation of beri-beri have been undertaken in recent years, but none of them in our opinion have appeared to offer such promising results as that which has been carried out under the direction of Dr. H. Fraser at the Medical Research Institute of the Federated Malay States. This inquiry was begun in 1907, and we published in THE LANCET of Feb. 13th of this year a preliminary report by Dr. Fraser and his colleague Dr. A. T. Stanton. The full report on the clinical portion of the inquiry was issued not long ago as No. 10 of the "Studies" from the Institute, and in it we were promised further details as soon as certain laboratory investigations were completed. This "clinical" report seemed to demonstrate clearly that beri-beri as met with in the Malay Peninsula is caused by the use of white, or uncured, rice as a staple article of diet. Some further interesting details have been recently published concerning the histological portion of the inquiry in the lately issued annual report of the Medical Research Institute for 1908. The chemical and pharmacological parts are, however, still proceeding, and for this reason, as also in view of the fact that it was thought advisable to repeat and confirm certain interesting observations already made, publication of the rest of the beri-beri report has been postponed for the present. Some particulars, however, are given as regards the histological examination of rice. By a particular process, the details of which are given by Dr. Fraser in the annual report, sections of the rice grains were made so as to secure comparison microscopically between white, parboiled, and other rice grains. In the first instance these sections were carefully examined to ascertain the presence or absence of moulds, with the result that in none of the sections prepared for examination could a trace of any mould be discovered. The sections showed distinctly the difference between white and parboiled rice. The latter in addition to the removal of the paleæ had most of the pericarp removed, while the white rice had the pericarp entirely, and the subjacent layers to a considerable extent, removed by the process of milling and polishing. As the aleurone layer in rice grains exists subjacent to the pericarp, it would appear on histological grounds, as had already been suspected, that the white rice is of lower nutritive value than parboiled rice. The chemical examination of the rice had shown that parboiled rice contained three times as much oil as the white rice. Sections of white rice, parboiled rice, and padi were therefore prepared by cutting the softened grains on the freezing microtome. These sections were treated with the various stains employed in the recognition of fats, and it was seen that oil was mainly confined to the layers immediately subjacent to the pericarp. As these layers are practically intact in the parboiled rice grain, and for the most part removed in the white rice, the reason for the difference of the two kinds of grains as regards oil is apparent. Since it might be contended that the treatment previous to milling might have rendered the proteid in parboiled rice more readily available than in the white rice, experiments were undertaken to elucidate this point, but they showed that no difference

rice grains. Thus it was demonstrated that nutritive differences, as regards oil at least, exist between the two sorts of rice; and with a view to examine the problem further from the dietetic point of view it was decided to extend the analyses so as to embrace all the articles of food habitually consumed by the Oriental races in the Malay peninsula. There the investigation now rests pending the publication of the chemical portion of the inquiry. That beri-beri should be caused by a deficiency in the amount of fat in the diet is no new idea. A French writer, quoted by Manson, propounded some time ago the theory that beri-beri was caused by a deficiency of fatty food-that it was, in fact, a "fat starvation." The disappearance of the disease from the Japanese navy after the substitution of a ration of fat pork for some of the rice dietary seems to give some support to this view. If the further investigations now being carried out in the Medical Research Institute of the Federated Malay States should prove this theory to be correct, the prevention of the disease in future, both on land and sea, would thus seem to be a comparatively easy task. The heavy financial losses which fall on employers of labour in the Far East and elsewhere from beri-beri sickness would as a result be greatly reduced, and much prolonged suffering as well as mortality would be prevented.

MEDICINE AND THE DAILY PRESS.

THE time has gone by when the discussion of any medical or sanitary matter outside the columns of a scientific journal should be regarded as an impropriety. On the contrary, with all sanitarians, we welcome the assistance of the greatest instrument for the formation of public opinion which the world has ever known, when that instrument is set in motion in a dignified and careful manner for the dissemination of useful knowledge. The good which the daily and weekly newspapers can do by bringing home to their millions of readers the well-ascertained lessons of hygiene and methods of preventing disease is enormous, and we have often admired the excellent reports of the proceedings of sanitary congresses and other gatherings of experts interested in public medicine which have appeared in non-technical papers. But there is an enormous difference between the temperate presentation to the general public of well-crystallised facts of scientific experience and the serving up of sensational tales of medical "progress" and discoveries that have leaked by devious paths from the laboratory or the lecture-room, and have not only gathered a thick coating of fiction but have lost their original nucleus of truth during their unfortunate passage to publicity. amongst them, because most cruel, are the tales of cancer and consumption cures which are so frequently given editorial sanction, though no attempt has been made to submit them to scientific criticism. Others less mischievous, but still unwarrantable, are the mutilated though highly decorated accounts of some lately devised system of treatment which before its proper application has been fully ascertained is recommended by its enthusiastic reporters as well-nigh a panacea. We need only mention the present fashionable "boom" in sour milk which has resulted from the publication of Professor Metchnikoff's views upon the attainment of old age by the device of policing the intestine with the lactic acid bacillus. When another useful and more recent method of treatment has filtered through similar channels to the public knowledge, horse serum and soda may become a fashionable pick-me-up before breakfast. Radium, of course, is well in the general eye and many regard it as an elixir of life. existed in the availability of the proteid in the two kinds of | The medical man watching the rising and waning of such

foibles of self-treatment may, indeed, feel with Puck, as to the inherent foolishness of mere mortals; but he can hardly acquit the newspaper press of being something more than accessory before the fact to their folly. Certain lay journals have recently devoted attention to the plenary sitting of the International Congress of Medicine for the discussion of appendicitis. Their readers have learned that the general feeling of that debate was against the operative treatment of appendicitis and that a reaction of medical men in favour of medical treatment is imminent. The impression thus given of what happened is quite wrong. What really did concern the Congress was not whether operations should be performed, but whether in certain cases they should be done in the "hot" or "cold" stage, which is. of course, still a matter of opinion. A general newspaper editor could not be expected to have such knowledge of medicine as would make him even acquainted with so technical a matter, in which case he would surely be well advised not to print any article dealing in popular language with the pathology and treatment of a serious and common malady without first passing it under expert and impartial scrutiny.

BRONCHO-BILIARY FISTULA DUE TO SCLERO-GUMMATOUS SYPHILIS OF THE LIVER AND LUNG.

AT a meeting of the Société Médicale des Hôpitaux of Paris on July 23rd M. J. Bruhl and M. Lyon-Caen reported a case in which a rare complication of syphilis occurredbroncho-biliary fistula due to gummatous disease of the liver and lung. The patient was a woman, aged 32 years, who was admitted into hospital on Nov. 20th, 1908, for enlargement of the abdomen and increasing expectoration of sputum of a greenish-yellow colour and bitter taste. At the age of 19 years she had been treated for syphilis at another hospital. Eight years before admission she had an attack of jaundice, and in April, 1907, she suffered from a painful crisis, simulating hepatic colic, with slight jaundice, but stools containing bile. From that time the patient knew that the liver was enlarged. At the same time as the hepatic symptoms pulmonary ones occurred. The patient had suffered from cough for five years and from hæmoptysis for two years. She wasted considerably, so that the symptoms suggested tuberculosis. In October, 1908, she expectorated a large quantity of a viscid greenish liquid with a bitter taste. On admission she was pale and wasted, but there was neither fever nor anorexia. The expectoration was nummular and muco-purulent and of a greenish tint. Under the microscope it showed neither elastic fibres nor tubercle bacilli. On staining with eosin a large number of polynuclear cells and greenish-blue crystals were seen. On macerating the sputum in a normal solution of soda clear greenish liquid was obtained which gave the reaction of biliverdin. Examination of the chest showed on the right side in front a zone of dulness continuous with the hepatic dulness, and behind an area of dulness at the apex, a resonant area in the middle, and an area of dulness in the lower half. On auscultation dry and moist râles of various sizes were heard. The abdomen showed above the umbilious a very developed venous circulation. There was ascites and the liver was much enlarged, its lower border being hard and irregular and descending five or six fingers' breadth below the ribs. In the left lobe could be defined a hard non-fluctuating painful tumour of the size of an orange. There was no jaundice. The spleen was enlarged and palpable. The stools were normal. The urine was of a mahogany colour and contained much probilin. Though the blood did not show eosinophilia hydatid cyst was suspected, but the reaction of complement fixation for

the echinococcus proved negative. Radioscopy showed a half obscure area at the apex of the right lung and two opaque areas—one near the spine and the other apparently in front of the stomach. The hypothesis of hydatid cysts therefore appeared to be confirmed. On Dec. 24th and the following days hæmoptysis occurred. On Jan. 8th the expectoration was of the colour of yelk of egg and contained much bile, and the dulness at the lower part of the right chest had disappeared. As there was evidently a communication between the biliary passages and the bronchi laparotomy was performed on Jan. 30th, 1909. Only an enormous lobe of Spigelius was found; the gall-bladder and bile ducts were normal. Death occurred eight days later. At the necropsy the liver was found very large and irregular and resembled a nutmeg-liver, but in three places hard whitish masses were seen which projected from the surface. The largest was of the size of a fist and adherent to the diaphragm and right lung. It was hard and fibrous and contained a large cavity which communicated with a biliary canal and also with the lung. The right lung was sclerosed and very little pulmonary tissue remained. Evidently the attack of jaundice eight years before was due to a growing gumma which compressed a large biliary canal, and the cough and first attack of hemoptysis were due to invasion of the lung by the gumma. M. Bruhl and M. Lyon-Caen could find on record only three other cases in which a gumma of the liver opened into the bronchi, though the coexistence of pulmonary and hepatic syphilis is well recognised. Mauriac and Fournier have described a thoracoabdominal form of visceral tertiary syphilis.

THE CHILDREN'S INFIRMARY AT CARSHALTON.

IT may be remembered that the Metropolitan Asylums Board constructed in 1902 a Southern Hospital to which convalescent cases could be drafted from its fever hospitals, just as other patients are now transported to the Northern Convalescent Hospital at Winchmore Hill. But circumstances change, and the hospital at Carshalton, which had already cost about £230,000, was never used, being left for six years in charge of a few workmen. Last year the Board determined to open the hospital in good earnest, not for fever patients, who are now well accommodated at Gore Farm, Dartford, but for sick and convalescent children under the age of 16 years. Many were the difficulties in making roads, in converting 100 acres of jungle land into green-sward and vegetable gardens, and in turning the buildings to a use for which they were not originally intended; but a willing committee, under the energetic and public-spirited chairmanship of Mr. E. S. Browne, gradually overcame them, and the new infirmary received the first batch of patients last January, though it was not formally opened by the President of the Local Government Board until June. Even now it has hardly reached its full strength of staff and inmates, but at a recent visit we saw some 735 children, at least half of whom were under the age of three years, collected from the infirmaries, workhouses, and schools of every board of guardians in London, except the City, which enjoys the rare privilege of barbouring but few sick children. It may be that the wide views of the neighbouring country are more appreciated by the staff than by the patients, but even little children are none the worse for being placed in a beautiful scene, while the high ground on which the buildings stand is exposed to sun and wind, which successfully bronze the children and give them voracious appetites. The Board has already provided four medical officers, 100 nurses (including 30 probationers), 19 laundresses aided by two men, and six sewing women. The institution is fitted with electric light, heating apparatus, sewerage, a telephone system, 150

clocks synchronised by electricity, and two electric motorcars for conveying food in hot-water tins from the central kitchen to the 24 bungalow blocks. Children requiring surgical treatment are housed in a two-storeved block which contains a well-fitted operating theatre, and, so far as is possible, patients suffering from various diseases are collected together in groups. Those children who are tuberculous, or suspected of becoming so, spend their days and nights in the open air under lean-to roofs. Boys who have reached the age of ten years are allowed the privilege of becoming scouts and of wearing shoulder knots; we saw some 30 of these scouts under the command of five patrol leaders, two of whom had lost a leg! They are allowed to drill, to build huts, and to make themselves useful in a variety of ways, while a body of girl "scouts" is engaged in sewing and other domestic work. Partly as a result of healthy occupation, the discipline and manners of the children seemed to be excellent, and no punishment more severe than being ordered to bed for a day or two has yet been found necessary. Most of the children looked very healthy, wore a happy expression, and seemed to be on the most friendly terms with the medical officers and nurses.

COSMIC INFLUENCES AND HEALTH.

WHEN regard is had to the number and intensity of great cosmic influences which are at work some wonder may well be expressed that the physical conditions of the world are as steady as they appear to be. It is only recently that the existence of fresh manifestations of forces affecting the earth has been realised, and it would be rash to say that of these manifestations there is no end. A fortnight ago we were told by our telegraph authorities that the whole earth was visited by a great magnetic storm. There were sudden rapid oscillatory movements of the magnetic needle, so erratic in character that the tracing could no longer be registered on the recording sheet, and in many instances the telegraph service failed. The duration of the storm was comparatively short, but whilst it lasted it exhibited an energy which has very seldom been rivalled. The year 1909 has so far been characterised in many parts of the world, including this country, by a very disturbed state of weather which has been uncongenial to everyone's health and comfort, and there are well-recognised authorities who trace this unpleasant fact to sun spots, the most recent of which has been calculated to be hundreds of thousands of miles in area. Magnetic storms have been ascribed to the same solar phenomenon, to a savage outburst of incandescent gases, and the world has been treated to a deluge of electrons. each carrying its electric charge to effect disturbances in the media they travel through, bringing about amongst other things the beautiful phenomena of the aurora and the magnetic storm. All this is interesting, and the interest intensifies when we consider that it is possible that these cosmic forces may have a profound influence on the health. No one can deny the peculiarly distressing effects which an impending thunderstorm has on some people and the relief they experience when the storm has spent itself. Many people assert that they experience a thunderstorm headache and can predict with confidence when the atmospheric stress is about to be relieved. It is also a fact, and not a sustic piece of oredulity, that beer or milk "turns" under these conditions, but no satisfactory explanation appears to be forthcoming of these events. They are, however, not more obscure than the colic, sickness, and diarrhosa which sometimes accompany electrical states. When we follow this vein of thought we become reluctant to deny the accuracy of many so-called superstitions. Is it quite incredible, for example, that some persons cannot sleep unless their body lies in the direction of the magnetic meridian or across it.

as the case may be? The conviction of this idiosyncrasy here and there has been so strong that revolving beds have been made which could be turned to the position conducing best to sleep. No one doubts that by some subtle power the moon influences the tides, and there is the probability of the existence of other commist influences of which so far we know little, yet which may interfere with our well-being. Certainly our wellbeing is disturbed by weather, and in that way, at any rate, we may trace certain disturbances of health to sun spots, since there seems to be little doubt that the meteorology of the earth is affected by them.

WILLIAM HARVEY'S ASSOCIATIONS WITH BIR-MINGHAM AND EDINBURGH.

In another portion of our present issue Dr. D. Fraser Harris, writing from Birmingham, sets forth at some length reasons for believing that in the year 1642 William Harvey spent a day or two at Aston Hall, near that city, in attendance on King Charles I. Dr. Harris has collected much information on other points in Harvey's personal history, and embodied some of it in a presidential address which he delivered last year at a meeting of the Scottish Microscopical Society. On that occasion he said that Harvey accompanied the King to Scotland in the summer of 1633, and that before leaving London it was necessary for him to apply for leave of absence from St. Bartholomew's Hospital and to have a deputy appointed. The King made this journey for the purpose of being crowned in Edinburgh. He entered the city in state by the "West Port," or "Gate," at the western end of the Grassmarket; the procession is known to have thence passed up the West Bow to the head of the Lawnmarket, and then down the High-street and Canongate to Holyrood Palace. Harvey must have traversed this route along with the King, and as the latter remained in Scotland until July 18th it is almost certain that Harvey spent about two months north of the Tweed. Of this there is indirect evidence, for Harvey has left on record the appearance of the Bass Rock "during the months of May and June" in a description he wrote of that island, which he visited for the purpose of studying the development of the embryo in the eggs of the solan-goose. It is not surprising that Harvey makes no allusion in his writings to the religious controversies which at this time were agitating Scotland, for his interests were so entirely professional that he even read Fabricius on generation during the battle of Edgehill.

CHRONIC CHOREA.

AT the Nineteenth Annual Congress of the Alienists and Neurologists of France and the French-speaking countries. held at Nantes in August (a note on which from our Paris correspondent will be found in THE LANCET of Sept. 4th). the subject of discussion in the neurological section was the chronic choreas. Dr. Paul Sainton of Paris accepted Brissaud's definition of chorea as consisting in "purposeless and seemingly causeless involuntary movements, occurring during both activity and rest, and consequently illogical and maladroit." This definition serves to render easy the differentiation of chorea from tic, myoclonus, athetosis, tremor, and rhythmical movements of hysterical origin. The clinical varieties of chronic chorea are Huntington's hereditary adult chores, chronic chores without the hereditary element, chronic Sydenham's chorea, and Brissaud's variable chorea. The pathological anatomy of chronic progressive chorea consists in inflammation of the meninges and convolutional atrophy, with occasional hæmorrhagic foci and areas of softening in the subcortical white matter and basal ganglia; microscopically, degeneration of the cells of the cortex, with interstitial inflammation and vascular sclerosis, is found. In the interpretation of these lesions there is much difference of opinion. Some consider the disease a circumscribed encephalitis, others a chronic diffuse interstitial encephalitis, others a neurogliai, and others still a vascular sclerosis: with one and all the clinical picture is identical. The pathogeny of chronic chorea is still vexed, and Dr. Sainton contented himself with the statement that the lesion of the nervous centres is one which is capable of emancipating the automatic motor centres. As for the familial element in the disease, it would appear to consist in a premature senescence of the cortical cell; perhaps this constitutes a locus minoris resistentiae for an inflammatory or degenerative process. Ohronic chorea must take its place in the category of diseases characterised by the combination of mental and motor symptoms, a combination which implies a physiologicopathological modification of the cerebral cortex. Thus it comes in line with the tics, with epilepsy and athetosis.

THE WEST AFRICAN MEDICAL STAFF.

In accordance with proposals made by the Departmental Committee on the West African Medical Staff, changes in the organisation of the staff are in contemplation which will have the effect of increasing the remuneration of medical officers and their prospects of promotion. In particular, ft has been decided that medical officers who have served for five years and are recommended for a higher rate of salary shall, after passing satisfactorily through a special course of study, be placed on the scale of salary rising by annual increments of £25 to £600. Certain sanitary appointments will also be created, with salaries of £600 rising to £700, or more. Full information as to these proposals may be obtained from the report of the committee, and the despatch from the Secretary of State in which the report was forwarded to the West African Governments. The report and despatch have been published as a Parliamentary paper. 1 Pending the receipt of replies from the West African Governments to the despatch forwarding the report, it has not been possible to revise this paper so as to include the new arrangements.

TEETH AT THE PENZANCE WORKHOUSE.

IN THE LANCET of Sept. 25th (p. 973) we commented upon the permission given by the guardians of Chichester Union to a tramp who desired to retain his tooth-brush and tooth-powder. We are inclined to wonder what would be the action of the guardians at Penzance in a similar case, for we read in the Daily Telegraph of Sept. 30th that "at a meeting of the board of guardians (at Penzance) a doctor recommended that tooth-brashes should be provided for workhouse children, but by a majority of five the board decided not to accede to the request." These enlightened gentlemen did not, perhaps, pause to consider that the physical health of the children placed by the law under their care is to be promoted and maintained by helping them to keep their teeth clean and sound, no less than by enabling them to wash their faces and hands. We pay the Penzance guardians the compliment of believing that they not only allow but compel pauper children to wash not merely their faces and hands but their bodies, and that they believe such abintions to be useful in maintaining health and in preventing future expenditure by guardians upon the care of the sick. The evil effects arising from neglected teeth are, we should have thought, even more obvious than the results of constantly neglected baths. However, the tramp entertained

at Chicester will, if he is well advised, avoid Penzance, and the guardians of that town may be recommended to study the Report of the Poor-law Commission.

THE LONDON MEDICAL EXHIBITION.

THE lines on which the London Medical Exhibition, now annually held in the Royal Horticultural Hall in Vincentsquare, Westminster, is organised are evidently appreciated by the medical profession, for each year there is an increasing attendance of our colleagues, not only from the metropolis but from the country also. The exhibitor, of course, regards the occasion chiefly from a business point of view, but if he does not succeed in gaining a result of practical benefit to himself he is, at all events, instrumental in bringing fresh advances in pharmacology, surgical and hygienic appliances, special foods and beverages to the notice of the visitor. One of the principal endeavours of the promoters of the scheme (that is, to make the exhibition of a purely professional character) has, it is stated, met with the most encouraging results. As far as possible the layman is excluded, and so no appeal is made to him in the shape of side attractions. In short, the exhibition is intended exclusively for the medical profession and this intention has been very generally appreciated. The proceedings this year have been marked by a standard still higher than previous years in regard to the character of the exhibits in general. Amongst the exhibitors were firms enjoying a leading reputation for the success with which they represent the great advances made in the preparation of fine pharmacological products, in the design of surgical and hygienic appliances, and in the manufacture of special foods and beverages. At times the place was animated by the various discussions going on between the medical practitioner and the man ready to supply him with the latest development. Last year the exhibition was attended by over 3000 London practitioners, besides a good number from the provinces, and the attendance this week promises to exceed that record. There seems, therefore, to be little doubt that medical men are glad of this opportunity to make themselves acquainted with the actual shape which the latest suggestions take, and which are likely to be useful to them in practice. The exhibition opened on Monday last and closed to-day (Friday).

THE LUNATIC ASYLUMS OF THE BOMBAY PRESIDENCY.

THE official reports of the public medical services in various parts of the British dominions are not all possessed of equal merit as contributions to medical knowledge. Sometimes they evoke hostile criticism in the local press, and a recent example of this kind is the triennial report on the lunatic asylums of the Bombay presidency. We have not seen the report in question, but it appears that a writer in the mail edition of the Times of India of August 14th complains that its pages are unduly filled with "almost endless tables of attenuated statistics and a considerable amount of other matter dealing with routine details," together with a corresponding deficiency of such descriptive comment on the details of the subject as might supply a kind of drapery or covering for the statistical skeleton. For instance, the report states that the total population of the asylums in 1908 was 1326 for the entire presidency. This strikes the critic as a very small number proportionally, and he complains that there is nothing in the report to show whether this figure represents anything like the whole of the existing insanity in Bombay. In his opinion a good deal more of the disease prevails, but the relatives of the sufferers keep them at home. Since the preceding triennial report was published the lunatic

¹ Cd. 4720, price 24d., through any bookseller.

population has increased from 1188 to 1326, 98 of the newcomers being males and 40 females. Out of the entire number under supervision 200 are classed as criminal lunatics. The information furnished regarding the causes determining the incidence of the lunacy is said to be very scanty. In conclusion, the critic draws attention to the difficulty which the asylum superintendents find in obtaining a satisfactory class of men for employment as attendants. This difficulty, however, does not exist merely in the Bombay Presidency, but is universal throughout India.

THE MUSEUM OF THE ROYAL COLLEGE OF SURGEONS OF ENGLAND.

THE Council of the Royal College of Surgeons of England has appointed Professor A. Keith and Professor S. G. Shattock to continue the series of demonstrations given in connexion with the museum. The museum demonstrations, which were inaugurated by the Council last year, were largely attended by medical practitioners and senior students, and were the means not only of making the contents of the museum better known, but also indirectly of adding valuable specimens to the collection. The present course begins on Friday, Oct. 15th, at 5 P.M., and is open to all medical students and practitioners on presentation of their cards. The Council of the College has made arrangements for the preparation of a new edition of the Catalogue of the Pathologcal Section of the Museum. The one at present in use was prepared 25 years ago by Sir James Paget, with the assistance of Dr. J. F. Goodhart. Mr. Alban Doran, and Mr. Frederick S. Eve. The new catalogue is to be written by Professor Shattock, with the assistance of Mr. Alban Doran in the Gynæcological series. A new edition of the catalogue of the entozoa is being prepared by Dr. R. T. Leiper; the last edition was the work of the well-known helminthologist Dr. Cobbold. Dr. Leiper has also rearranged and made many additions to the collection of entozoa in the College collection. The acceptance by the Council of the College of the large collection of specimens belonging to the Odontological Section of the Royal Society of Medicine has entailed a considerable structural alteration and extension of the museum. The odontological collection, which has been accepted by the College as a trust, comprises nearly 5000 specimens and requires a special room for its display. It is proposed to add the odontological specimens already in the College museum, many of them being preparations made by Hunter to illustrate his classical researches on the teeth, to the collection now accepted on trust. The combined collections will make the most extensive and most valuable odontological museum in the world and will prove a boon to all English odontologists engaged in study and research. It is hoped that this new section of the museum may be arranged, labelled, and completely catalogued during the present

THE MANCHESTER AND SALFORD SANITARY ASSOCIATION.

The report of the Manchester and Salford Sanitary Association for 1908, which has been recently issued, shows that the work of the association is making good progress. Various matters affecting health came under review during the year, two of them being Nature Teaching in Schools and the Town Planning Movement. It was in Manchester that the town planning movement was started, and it still receives the attention of the committee, although the Bill introduced by Mr. John Burns, President of the Local Government Board, to give town councils special powers with a view to preventing the creation of slums, has been to a great extent modified. The supply of cottage baths and washhouses has not been advanced beyond the two that were established

many years ago, notwithstanding their great and continued success. It is consoling, however, to learn that a deputation to the Baths Committee was told that a good deal of work in the adoption of sites had been done, and that an early extension of the scheme may be looked for. In the meantime money has been lavishly spent in the erection of swimming baths with luxurious accommodation and decorative exteriors, but it is a question whether these magnificent structures add as much to the comfort and health of poor families as the unobtrusive baths and washhouses hidden away in unimportant streets. Simultaneously the increase of the rates seems to be forgotten, as well as the invariable sequence that slums increase as the rates go up. Mr. William Thomson, F.C.S., is engaged very usefully for the association in an examination of the quality of the gas supplied from the gasworks. There has been great deterioration of it since the introduction on a considerable scale of water-gas without any corresponding reduction in the price and with increased risk of gas poisoning. The committee recently passed the following resolution, viz. :-

That having regard to the acknowledged deterioration of the physique of a large proportion of our people this association urges upon the authorities that the time has come when the youth of the country should be required to submit to systematic physical training up to the age of 22.

The association recommends service in the Territorial Army as one means of effecting the desired improvement of our national physique, and there appears to be no doubt that military training and drill are more successful in improving the physical condition of a young man than the mere playing of games. It does not speak well for the general interest in the association that the list of subscribers is so small. This is to be regretted, for if a considerable proportion of the people could be persuaded that the sanitary condition of the city is a matter of public concern sufficient numbers of small subscriptions would come in to put the association into a satisfactory financial position. "Health Lectures for the People" are still given and published at a very cheap rate, and at the conclusion of the annual meeting Mr. H. W. Norman, L.D.S., delivered an admirable address on "The Condition and Treatment of the Teeth of our Public Elementary School Children."

A RETURN prepared by the Inland Revenue authorities shows that the numbers of licences at 5s. each issued to makers or vendors of patent medicines in Great Britain (the duty not extending to Ireland) were in 1898-99, 33,992; in 1899-1900, 34,554; in 1900-01, 34,698; in 1901-02, 35,364; in 1902-03, 36,366; in 1903-04, 38,462; in 1904-05, 40,129; in 1905-06, 40,734; in 1906-07, 41,353; in 1907-08, 42,272; and in 1908-09, 42,563.

AT a meeting of the Medical Society of London to be held on Monday, Oct. 25th, Dr. F. W. Hewitt will read a paper on the Need for Legislation in Regard to Anæsthesia and the lines upon which such legislation should take place. As the whole question is one of great importance to the medical profession and one on which opinion is sharply divided an interesting debate should follow.

THE Governor of Mauritius in a telegram to the Secretary of State for the Colonies has reported 26 cases of plague with 14 deaths during the week ending with September.

THE death has occurred of Dr. William Rivers Pollock, obstetric physician to Westminster Hospital, who was 50 years of age.

WE regret to record also the recent death of Dr. Edward Clapton, formerly physician to St. Thomas's Hospital, who died at Lee in his eightieth year.

THE POOR-LAW MEDICAL SERVICE: COMING LEGISLATION.

BY WILLIAM HOLDER, M.R.C.S. Eng., J.P.,

MEDICAL OFFICER AND PUBLIC VACCINATOR FOR THE SUTTON DISTRICT OF THE SCULCOATES UNION; LATE SURGEON TO THE HULL AND SCULCOATES DISPENSARY.

THE speeches in the House of Lords on the recent Reports of the Poor-law Commission mark "footprints on the sands of time." The head of the State Church, the Archbishop of Canterbury, was roused to press that the conclusions of the Commissioners should not be disregarded or delayed; and the leader of the Government in that House, Lord Crewe, said significantly: "The system [Poor-law Act Regulations] of 1834 had reached its limits, and if there was to be any real improvement we must look to something else," and followed his words by the declaration that "this was a vast subject, but not too vast to be dealt with within the immediate future." This is all the evidence we need that vast changes affecting the medical profession are imminent. It therefore behoves the profession, as a trusted body of the State, to interest itself in the matter, to study the subject, to determine its policy, and to advise the State on matters in which nearly 4000 medical men are personally concerned, and about which they have the most intimate knowledge. The members of the medical profession as a general body may then be asked to act as faithful allies to their colleagues of the Poor-law Medical Service and to give active support to any well-considered scheme that may be forth-coming to put the Poor-law Medical Service in a more efficient position.

The two reports of the Poor-law Commissioners are very searching. Some member or members of that Commission must have had practical knowledge of the difficulties and deficiencies under which Poor-law medical officers conduct their efforts and must have effectively impressed the signatories of both the Majority and Minority Reports with the gravity of the position and the needs for recognition and help of the medical part of Poor-law management.

Whoever took this line, let us not forget to be grateful.

On all hands the importance of these two reports is

granted, and this by no class more freely than by the many boards of guardians who have, on the whole, humanelyfar as their knowledge went-carried out the system of the 1834 Act. These boards have, at any rate in some of our larger cities, endeavoured to meet, by extended help to the poor, the developments which increased wealth and wider intelligence have given to the country. In the treatment of the sick, unfortunately, many boards have made no movement, but since these reports have been published numerous guardians have read them and having enlightened themselves are showing a willingness to profit by the lessons. Certain boards of guardians have submitted questions to their medical officers asking for information and for suggestions as to the management of medical matters and the regulations of areas—a thing never done before. As all amendments of a law must be founded on experience of defects in its working, it may not be unhelpful to lay before the profession a series of queries put by one board of guardians to the district medical officer, and the replies of that officer who has had charge for over a quarter of a century of one of the largest districts in one of our great cities.

Letter from the District Medical Officer of Medical Relief District No. —— of the —— Union to the Clerk of the —— Board of Guardians.

MEDICAL RELIEF DISTRICT No.

MEDICAL RELIEF DISTRICT No. —.

[The letter commences by the medical officer explaining that it has been his duty as a member of the Council of the Poor-law Medical Officers' Association, not only to read the Reports of the Royal Commission, but to attend a National Conference of the Poor-law Medical Officers' Association at which Commissioners who signed both Reports read papers expounding the medical aspect of their respective views, and also to read the memorandum of the chief medical district inspector of the Local Government Board. He has thus learnt something of the tendency of the legislation which is coming. But if the Commissioners, after five years of industrious endeavour, admit their conclusions are incomplete, it cannot, he submits, be expected that within the limits allowed he can cover the complex medical problems which are involved in the questions. He continues:—]

The most prominent trend of change in the District Medical Service is to bring the district medical officer's work into relationship with that of the sanitary medical system of the locality in which he acts. The management of poverty and its disease causes is so blended that the separation of the district medical officers from the control of the

guardians is unlikely; but a practical defect is felt—viz., that district medical officers see insanitary causes, such as filthy homes, defective privies, blocked and broken sinks, verminous dirty persons, slovenly dirty mothers, in untended houses in which are children with suppurating eyes, and even contaminating diseases, such as chicken-pour and other important causes, inviting, originating, and continuing disease; and yet though seen and deplored by district medical officers as a cause of poverty, they (the district medical officers) are out of the machinery which removes them. They have no duty to report them to the sanitary authority.

This evidences want of some official link between two departments doing related yet now separated work. There should be some connexion between these two offices in the interest of the ratepayers as well as the poor themselves.

I answer the detailed questions:—

QUERY 1.—So far as your district is concerned, do you think that

doing related yet now separated work. There should be some connexion between these two offices in the interest of the ratepayers as well as the poor themselves.

I answer the detailed questions:—

QUERY 1.—So far as your district is concerned, do you think that the present boundaries and arrangements are conducive to a satisfactory administration of relief to the sick poor?

Answer 1.—The arrangements are not conducive to a satisfactory administration of relief to the sick poor.

(a) The sanitary services are too related in work to be separated in action.

(b) When a severe epidemic arises some automatic method of supernumerary temporary assistance should be provided; and as the district medical officer is the first in the field to note an epidemic originating and advancing, and the best qualified judge of its causes and its virulence, he should be officially authorised to send his valuable information to the sanitary authority, otherwise the sanitary authority can only generally be informed of a coming epidemic by an advancing death-rate or defective school attendance.

(c) The closing entirely of the relief office for so long a period as from Saturday noon to Monday morning is a defect to be remedied. I am making no reflection on relieving officers. They are kindness and consideration itself to the poor, and in this Saturday to Monday interregnum, when they are found, they readily sacrifice their leisure to meeting all necessities; but many cases occur when poor persons do not know where to get orders for medical attendance. The district medical officers, if they hear of the case, attend without an order, but the poor have some difficulty in understanding this.

(d) "Not on the book" orders should be recognised and paid for as extra medical work. There is no doubt much suffering caused to honest poor persons, temporarily down on their luck, unable to pay reasonable charges for efficient medical attendance, who are unable to obtain infirmary or dispensary orders. These people might fairly have medical attendan

medical omeer when the outer fringe of his district, if bordering on open lands, has its population greatly increased.

(ii) In fixing the remuneration for each boundary the poverty of a district should bear reasonable relationship to the number of its likely sick poor.

QUERY 2.—Is the present arrangement for the supply of medicines, dressings, &c., satisfactory in the interests of the patients and suitable to their necessities? Would you advocate the establishment of district dispensaries, to be maintained by the guardians, where sick paupers could be supplied with medicines, &c., on the written recommendation of the district medical officers?

Arswer 2.—The present arrangement for the supply of medicines, dressings, &c., is not satisfactory in the interests of the patients or suitable for their necessities or cure. The modern aseptic dressings, atc., is not satisfactory in the interests of the patients or suitable for their necessities or cure. The modern aseptic dressings, atc., is not satisfactory in the interests of the patients or suitable. For their necessities or cure. The modern aseptic dressings, actiseptics, gauzes, &c.; the modern mapticines; the serums, liquid animal extracts, new chemical synthetical compounds, and other modern expensive helps, which shorten many illnesses, are a serious cost, one prohibitive to the district medical officer. This unreasonable charge on the doctor invites neglect or dulls his perception of the extensive and proper use of new remedies. It is but natural, he feels, that the guardians should pay him at least the average of what the average patient costs in medicines and appliances in the house if they wish him to treat his cases according to modern methods. I have tried to keep my conscience clear and to forget my pecuniary penalty for doing right, but I must say that when I have had to send a pound of absorbent wool, a roll of absorbent whole, a roll of compan

be paid by them.

The foregoing are reasons why the establishment of district dispensaries for the dispensing of drugs and appliances, found and paid for by the guardians, is necessary. I would, however, like emphatically to say—such places should be dispensing places only, and not outdoor departments, that is, dispensing and consulting establishments combined; for there the slok, siling, weakly, malodorous, expectorating hordes are huddled together for long periods, waiting, in depressing companionship for consultations, later to be huddled into other seats

to wait a further long period for medicines to be dispensed. Definite consultation hours at the surgery of the district medical officer is a ranch better arrangement. The medical officer is to be found there; he gives two hours daily at his house, 9 to 10 in the morning, and 5 to 6 in the evening, for consultations, taking messages, and giving certificates. At the dispensary only one hour daily is generally given. The sick at the surgeries of the district medical officers are better separated than at the dispensaries, and after seeing the medical officer they would walk a little way to the dispensaries—which should be central to the districts concerned—and there get their medicines from a dispenser. At the surgeries of district medical officers patients are less huddled together. The doctor can give them more time and attention and keep better continuity with the case, and, what is more important, in emergency the sick quickly get at him at any hour of the day or night at his known residence. There is no need to wait until the dispensary opens again to communicate with him.

QUERY 3.—Can you suggest any improvement in respect of the subject-matter of Query No. 1 or Query No. 2? If so please state fully in what direction.

Asswer 3.—My suggestions are as given above.

QUERY 4.—Do you consider the ciercal work attached to your office is unnecessarily extensive? Do you carry out fully the requirements of the Orders and regulations of the Local Government Board, &c., in respect of the following matters?

(a) Sending of notices to local health authority in case of contagious, infectious, or epidemic diseases. (A.O., February 12th, 1879.)

(b) Keeping of the "District Medical Officer's Relief Book." (A.O., February 28th, 1886.)

(c) Giving of certificates specifying the ailments of paupers attended by you, when requested by the relieving officers or the paupers themselves. (G.O., July 24th, 1847.)

omcers or the paupers themselves. (G.O., July 24th, 1847.)

INVER 4.—Undoubtedly some clerical record of our work is necessary, but some of the present records are unnecessary, irksome, and take up time that might be more profitably used. I have had over 30 years' experience of parochial and parish district and hospital work in many counties in England. I never knew a parish medical registers are not examined properly at the board room hence the doctor feels his time is too important to be wasted, and thinks it is not necessary to fill in every visit or bottle of medicine. He feels that a record of visits, of medicine given, or of surgery attendance generally is sufficient if it shows reliable attention. In the days when unqualified assistants were kept it might have been necessary to use red instead of black ink to distinguish between his work and the principal's, but in these days, when all visiting assistants and partners must be fully qualified, and have to be accepted as deputies, it is needless, trictly attend to (a) so far as the Infectious Diseases Notification Act requires; I attend to (b) except that my dispenser copies from my daily visiting book and keeps the record of medicines dispensed; and (c) Yes.

**Exay 5.—Any general observations, remarks, or suggestions as to

from my daily visiting book and keeps the record of medicines dispensed; and (c) Yes.

Query 5.—Any general observations, remarks, or suggestions as to the treatment of the sick poor would be appreciated.

Answer 5.—It is only fair that the district medical officer should be paid by salary for his professional services, and not have to find drugs and appliances. It is better he should be a part time officer in general practice—a doctor of standing and experience in the district—that is, if he is to have influence with the dirty and improvident. The knowledge of the usefulness and indusone of the district medical officer over the poor is much misunderstood. His work is as often to stay poverty as it is to cure disease. Poor patients do accept advice from the doctor they would refuse from others; they look on him as their friend, confidant, and adviser. He understands their misfortunes as well as their ills, and their weaknesses of temperament, which form the key of many of their improvident deficiencies. They trust him because he is by training no supercitious puritan in judging them. This reliance on the doctor and his disinterested advice could be used to the greatest amelioration of poverty and sickness. He might be made what the State has wisely directed school medical officers to make themselves—viz., a "pervading influence." His education and professional skill gain the respect, I had nearly said reverence, of his poor, and should demand that he be recognised as a man worthy of proper reward. His work does not begin at 9 A.M. and end at 5 P.M., as ordinary workers, with half Saturday and Sunday for rest. His duties begin at 9 A.M. on Monday morning and continue might and day to the following Monday. He has no yearly holiday allowed. This injustice has never been squarely faced by guardians. Services begun by the profession, as benovolent aids to the poor, have been accepted as a right. The strained labour of the profession has been accepted without scruple. I respectfully hope the guardians will not allow

mow that, without the interference of the patient district medical officers, the inquiries of the Commission have called out against this abuse.

he salary should be adequate and not stinting. The work is heavy, exacting, and noble. Properly recognised, it is certain the service will see removed the reproach, "he is only the parish doctor." This is never uttered by the poor they serve, but by the richer people who do not see his work or sacrifices in a field where he has to do all the details, which in Lospitals nurses and attendants do for the medical man.

15 must never be forgotten that medical skill is, and will ever be, diagnostic, and not mechanical or stereotyped. Cases cannot be treated wholesale; each case requires original research and thought. Each case is a problem in itself; proper diagnosis is the key to short illness, and proper treatment by food, medicine, and sanitation shortens the period of parish relief in acute cases and prevents its recurrence.

In the Poor-law Commissioners' reports the suggestion of blending parish patients with contributory patients in a part-charity supported inattution will do harm. The suggestion is the outcome of the London system of contract practice, and of club practice in the provinces, both practices unworthy the profession and the patients. If such are established they will increase the

area of pauperism, degrade those who can pay, and stop the flow

area of pauperism, degrade those who can pay, and stop the flow of benevolence.

I venture to suggest much more generous doles to respectable aged widows and mes, especially valetudinarians. The most helpful thing would be the building of self-contained two-storey houses with open gardens, such as I have seen in Holland. Then, after classification, two or three persons of the same sex could be placed rent free in one of these domiciles or flats. The combined allowances of three persons would be spent more economically. For instance: one fire, one pie, one boiling of potatoes, one light; and many other things might be enumerated where one would serve three persons collectively better than three single persons in three rooms. Another advantage of this conjoint domicile would be that all would have companionship and show compassion one to the other in the passing sicknesses of ago. They would give ordinary nursing to each other in slight indisposition. One or two rooms at the end of the buildings could be made into wards for more serious cases, requiring more serious nursing. If this was not more economical, it would at least take away the self-reproach one often feels because the stinted allowance given to respectable out-door aged men and women paupers is insufficient to keep them well, or to help them when they are lik.

More power is needed to get cleanliness in some houses and from some parish patients. Slatternly homes beget slatternly children, and they become slatternly mothers of future slatterns. Whilst seeing failure in dragooning the indolent into cleanliness, a system of loans of cleaning materials and of payment for scrubbing and whitewashing I am sure would have a two-fold effect. It would make the recipients of the loans feel they were earners, and often teach good habits, some of which would stick.

The present method of mending disease and leaving the originating causes to act again is indefensible. The Poor-law medical offices.

they were exercis, and often teach good habits, some of which
would stick.

The present method of mending disease and leaving the originating
causes to act again is indefensible. The Poor-law medical officer
as a sanitary adviser could get much carried out better than
other officers. If tactfully managed the poor would accept
advice from the doctor better than from any other person.

I would like to say how impressed I am with the good effected in
placing out nurse children with aged women. I know several
instances where the foster boys have been all a son should be to
an aged mother and where the woman has lavished her
solicitude on the children's morals and worldly improvement
with the greatest success. In fact, I have never known but one
failure to get the greatest benefit and blessing to child and
foster-parent in these cases.

May I lastly appeal to the guardians to increase the fee for attendance on parish patients at accouchements. It is not fair or
reasonable to pay a fee below that paid to the midwife. The
task is not the ordinary attendance. The work is done with
often little light. The patient has few clothes and no cleanitness. The doctor sits hour by hour through the silent watches
of night, saving life and helping the weak and suffering, and
may demand a reasonable reward. District visiting nurses
should be provided for accouchement cases. Such nurses should
be exclusively used for labour cases. They should not be
employed in drossing wounds or ulcers or in surgical cases.
They should act solely under the direction of the doctor in
charge. It may be accepted as a fact that these nurses have a
greater influence on the habits of the poor than is supposed.
They shoult he helpless how much nicer home is when clean,
and their influence for good in many ways reaches far outside
their passing visit and example.

Finally, the fees for extra surgical work require readjusting.
I have written fully because I feel legislation is coming on some
of these lines.

Neither the questions of the Board of Guardians nor my answers, which in this publication of them have received a certain amount of emendation, cover the whole subject, but they mention many practical points and suggest some I submit them as a contribution to the comremedies. plete discussion of the subject to which the columns of THE LANCET are clearly open, and with the idea that they may stimulate others who are directly interested towards some prompt and common course of action.

OPENING OF QUEEN ALEXANDRA SANATORIUM, Davos.—The British sanatorium in the Alps, for the successful completion of which the unceasing labour of the local secretary, Mr. H. C. Wrinch, has mainly to be thanked, will be open for the reception of patients at the end of this month, although the inaugural ceremony is to be postponed until the winter season. On the visiting staff are Dr. W. R. Huggard, H.B.M. Consul in Davos, Dr. Arnold F. Bill, and Mr. Florian Buol; and the resident staff consists of Dr. Joseph W. Noble as medical superintendent, and Dr. James Fairley as junior resident medical officer. The matron, Mrs. Teesdale, who for some years past had the entire management of the Davos Invalids' Home, will be assisted by a small staff of English nurses with home sanatorium training. Although each patient occupies a separate room, the inclusive charge is only to be 38s. per week. Only early or convalescent cases are eligible. A large number of applications having already come in, candidates should not delay obtaining forms from the local secretary in Daves, Mr. H. C. Wrinch, or from the honorary secretaries in London, Dr. William Ewart, 31, Upper Brookstreet, W., and Mr. D. A. F. Vesey, 3, Camp View, Wimbledon Common, S.W.

THE VACCINATION ACTS AND THE GROWTH OF "CONSCIENTIOUS OBJECTION."

By LEONARD B. CANE, M.B., B.C. CANTAB., M.R.C.S. Eng., L.R.C.P. LOND.,

ASSESSMENT PETEROLAN TO THE PETERBOROUGH INFIRMARY; DEPUTY PUBLIC VACCINATOR FOR THE PETERBOROUGH UNION,

THE effect of the recent changes in the Vaccination Acts upon the number of vaccinations has been already very marked. An examination of the returns for Northamptonshire reveals an enormous increase in the relative proportion of unvaccinated children, and there would seem no reason to doubt that the same tendency exists throughout the country.

The history of vaccination since its discovery as a prophylactic against small-pox over a century ago is so well known that I need only mention one or two salient points. In 1718 inoculation with small-pox virus was introduced from the East and became for a time very popular, especially after its adoption by members of our Royal Family, but unfortunately the artificially produced small-pox was found to be not only infectious but by no means free from danger to the subject of inoculation. For some time, however, cow-pox had acquired the reputation amongst West-country farmers of affording protection against the more serious disease; and in this belief one of them, Jesty by name, in 1774 actually inoculated members of his family with fluid from cow-pox vesicles. It was not, however, until 20 years later that this tradition was made the subject of a scientific inquiry by Dr. Jenner. In 1798 Jenner published the results of his investigations, and was supported two years later by leading members of the profession in London, and in 1802 by a Committee of the House of Commons. In 1807 the Royal College of Physicians issued a report based upon the results of several hundred thousand cases, to the effect that the protection afforded by vaccination, though not absolute, was a great security against the incidence and severity of small-pox, and that the process was in no respect injurious. Similar reports were issued also on the continent, with the result that in Denmark vaccination was made compulsory in 1810, in Sweden in 1816, and in Germany compulsion was subsequently extended even to revaccination. In every country of Europe and in America the practice spread rapidly. In England, however, it was not until 1840 that an Act was passed to provide the means of vaccination at the public expense, and even then compulsion was postponed for another 13 years. In 1853 an Act making postponed for another 13 years. In 1900 at Act making vaccination compulsory was passed without opposition and it continued in force, with minor alterations and amendments in 1858 and 1867, until 1898.

By the Act of 1867, Section XXIX., every parent or

By the Act of 1867, Section XXIX., every parent or guardian of a child was rendered liable to "a penalty not exceeding twenty shillings" for neglect to take a child to be raccinated and subsequently inspected, unless he offered "a reasonable excuse for his neglect." It was not sufficient to have a general objection to vaccination, but the parent had to show by legal evidence satisfactory to the magistrates that he had good ground for believing that in that particular case vaccination would be injurious.

In 1898 the Royal Commission issued its report, as a result of which calf lymph was substituted for arm-to-arm vaccination, and the "conscientious objection" clause was made law.

According to the Act of 1898, Section II., i., "no parent or other person shall be liable to any penalty if within four months from the birth of the child he satisfies two justices or a stipendiary or metropolitan police magistrate, in petty sessions, that he conscientiously believes that vaccination would be prejudicial to the health of the child, and within seven days thereafter delivers to the vaccination officer for the district a certificate by such justices or magistrate of such conscientions objection." By this Act the parent was entitled to exemption if he satisfied the mugistrate that he believed vaccination to be injurious whatever his ground for such belief might be. This Act came into force on Jan. 1st, 1899, but the above section in August, 1898.

By the Vaccination Act, 1907, Section I., the parent is no longer required to appear before a magistrate to satisfy him either that he has a well-grounded (cf. 1867) or a possibly ungrounded (cf. 1898) belief that vaccination would be

injurious to his child, but has merely to make "a statutory declaration that he conscientiously believes that vaccination would be prejudicial to the health of the child, and within seven days thereafter to deliver or send by post the declaration to the vaccination officer of the district." This Act came into force on January 1st, 1908, but a temporary Order to the above effect became law in September, 1907.

With this brief history in mind we can better review detailed statistics. The effect in the Peterborough Union of these changes in the law is shown in the accompanying table, in which the percentage of births in respect to which exemption orders have been obtained is shown for each half-year since the creation of conscientious objection by the act of 1898.

TABLE A.—Showing the Growth of Conscientious Objection in Peterborough.

The table has been compiled from the half-yearly returns and not from the more accurate supplemental annual returns, in order to show the immediate effect of measures which came into force in the course of the year. In the final completed returns the number of certificates of objection received is in almost every instance slightly in excess of those noted in the preliminary half-yearly returns. These totals do not include the considerable number of cases which escape vaccination in some other way, either by refusal, by ill-health or death, or by removal to another district. It will be seen that since the important change made by the present Government in 1907 the growth of conscientious objection has been extremely rapid. Nor is the state of vaccination in this union by any means an isolated instance. The half-yearly figures for most of the other unions of Northamptonshire show a similar tendency. (Table B.)

TABLE B.—Percentages of Births in respect of which Certificates of Exemption have been received.

Unions of the County of Northampton.		1903	1904	04 1905	1906		1907		1908	
Brixworth	14-4	18.3	20.3	19.6	18-0	24.1	27.1	24-5	36-9	40-4

Pry's Law of Vaccination, seventh edition. 2 Ibid

Doubtless similar results are obtainable throughout the country. It requires therefore but little imagination to foresee a time when vaccination will have become once again the exception rather than the rule. Already it is practically a voluntary act and parents are no longer required to show acquaintance with even the most elementary arguments for or against it, nor need they understand either the nature of the process or the reasons which have led to its adoption.

As Dr. T. Claye Shaw said, in a recent address: "We have remedies to hand which we know to be antidotal to certain contagious and infectious diseases, and yet we allow sentiment and ignorance to override the accomplished facts of science, and we place in the hands of illiterate obstinates the means of obtaining exemptions from treatment by the permits of a lay, and possibly a prejudiced, authority." In these circumstances it is difficult to justify the large expenditure of time and money entailed in carrying out the Acts.

The attitude of the Local Government Board is inconsistent. Compulsory vaccination is either a protective measure beneficial to the whole community, or an act of doubtful utility imposed against the will of a large section of the people, to whom it appears but an unwarranted intrusion of an officious State into the freedom of the home. latter, then these laws are unjust, and the sooner they are repealed the better it must be for all; but if the Government really have faith in the experience of practically the entire medical profession, both in this country and abroad, and the conclusions arrived at by its own Royal Commission after nine years' continuous investigation, then it is its duty to safeguard the national health by increasing the stringency of the vaccination laws, so that in this country, as elsewhere, the disease which until a century ago was such a terrible scourge may be entirely stamped out, and the risk of such an expensive outbreak reduced to a minimum.

In conclusion, I wish to express my indebtedness to Dr. Charles E. Paget, medical officer of health of the county of Northampton, for his courtesy in allowing me the use of his published and unpublished returns up to the end of 1908, and to the vaccination officers of the various unions for supplying me with the most recent statistics for the purposes of this paper.

MOTORING NOTES.

By C. T. W. HIRSCH, M.R.C.S. Eng., L.R.C.P. LOND.

The Latest 10-h.p. and 15-h.p. Napuer Cars.

RECENTLY the writer was afforded an opportunity of examining and testing the latest versions of the Napier factory. Messrs. S. F. Edge, Limited, have for many years manufactured high-powered automobiles, and now in addition they are devoting their attention to the development of cars more suited to the pockets as well as needs of the medical profession. Prior to setting out on the trial run a rapid survey of the chief features of the vehicle was made. The fly-wheel is in front, so that 10 inches clearance is given, which owing to the position of the fly-wheel, is equal to at least 12 inches in a car of ordinary design, where the fly-wheel is behind the engine; the reason is that in driving this car over rough roads with lumpy surface, when the front wheels ride over an obstruction they lift the flywheel with them, as it is in front of the engine, whereas, when it is behind, the front wheels after riding over the lump drop the fly-wheel on the top of the rise. The engine. clutch, and gear-box are constructed in one unit; this permits of a three-point suspension, and ensures the absolute alignment of engine, clutch, and gear-box under all stresses or strains of the chassis. The clutch on the 15 h.p. is of the multiple disc type, and consists of metal to metal plates running in oil; it is placed in front of the gear-box, in fact is a part of it, but there is a septum between the two, so that the gear-box lubricant cannot enter, otherwise, of course, grit or chippings from the gears might pass in and cause damage to the plates. On the 10 h.p. a metal cone clutch is fitted. The 10 h.p. has a two-cylinder engine cast in one; the 15 h.p. has a four-cylinder engine, with the cylinders arranged in pairs. The cam-shaft and all the gearing are entirely enclosed in an aluminium and dust-proof

oil-retaining case. One cam-shaft operates the inlet and exhanst valves, and they are interchangeable. The valve lifters have rollers where they come in contact with the eccentrics and are very solid forgings. Plates that can be easily detached are placed in front of the valve spindles and tappets, thus rendering them secure from dirt and foreign bodies. The crank runs on roller bearings, and these are well lubricated by splashing, as also are the pistons and gudgeon pins. Three rings are fitted to each piston; they are pinned, which absolutely eliminates all possibility of their working into line, but if the owner does his own repairs he may experience a little trouble when replacing his cylinder covers after lifting them off to remove carbon deposit, as the rings may ride on the pins. Still, with a little care this can be avoided.

Lubrication is by a gear-driven pump and the surplus oil is returned to the sump, from which the pump feeds, through a wire gauze strainer. In addition, an aluminium lubricating disc is attached to each web of the crank, which contains a scroll-shaped channel, very wide at the periphery of this ring and getting gradually smaller towards the crank-pin, which it enters through holes drilled for the purpose; oil is continuously pumped to the mouth of this channel, and is finally thrown out through the connecting-rod bearings by centrifugal force. A gauge is attached to the dash which verifies the correct working of the pump and lubricating system. The whole arrangement is economical and should prevent both under- and over-lubrication. A gear-driven centrifugal pump circulates the water, the pipes are of ample size, the radiator is efficient, and the valve ports of the engine are jacketed, so that overheating is well guarded against.

Ignition is by a Bosch high-tension magneto, which can be easily and rapidly detached and replaced, for by merely slackening of a thumb screw the stirrup which holds the magneto down on its bed can be removed and the magneto lifted straight out of its coupling. On the majority of these cars a magneto with a fixed firing point is supplied, but the makers will, if requested to, fit one with a variable timing arrangement, or what is even better, the Bosch dual igni-This gives the advantage of a separate high-tension electric system and greatly facilitates starting, enabling the owner, when making short stops, such as a doctor does when calling professionally, to start off on the switch. It can also be used as a stand-by ignition in case of need; with it a coil and battery must be carried, but the magneto contact-breaker and distributer is employed in place of a separate commutator. The petrol is supplied by gravity, and I believe it would be an advantage if the petrol tank stopper was tapped to take the end of the tyre pump; then on a hill, if the quantity of petrol is low, the tank could be rapidly inflated and the carburettor kept supplied by pressure.

The carburettor has an annular float, which ensures a regular petrol level in the jet, no matter at what angle the chassis may rest, and the opening of the air-valve in the mixing chamber is governed by the speed of the engine. For ease in starting an arrangement is fitted on the dash to close the airport below the jet, and an agitator can be worked by a rod that protrudes near the starting handle, so as to flood the float chamber on starting, and this obviates the need of opening the bonnet when this is needed. Three speeds forward and a reverse are supplied. The top drive is direct from the engine to the differential, without the intervention of any gear. In lieu of the usual dog clutch the two portions of the first motion shaft are made one by a pinion being fixed to one half, which engages with internal teeth on the other part. The change gear is on the now popular gatechange system; the advantage of this over the notched quadrant is that it is a more certain method of locking the gears; it also reduces the length of the gear-box, and enables the driver to slam the change-speed lever forward or backward safe in the knowledge that he has no notches to feel and possibly to overrun. Those who, with the quadrant variety, have through carelessness notched and spoilt their dog clutch on the top speed by letting the clutch in before getting the lever right home, will appreciate this. throttle is controlled by a foot pedal situated near to the clutch; a spare control, working on a sector on the dash, is also fitted. Two independent sets of metal to metal brakes are provided: the foot one acts on the main shaft and the hand one on the hubs of the two back wheels; both are thoroughly protected from dust

^{3 &}quot;On the Span of Life," Midsessional Address, delivered before the Abernethian Society, June 24th, 1909, St. Bartholomew's Hospital Journal, August, 1909.

and mud, and an accessible method for adjustment by hand This is very important, as I have noted on many cars that the brakes are frequently not maintained in a state of efficiency, merely because the adjustment is difficult to get at. The frame is of channel section steel, narrowed at the forward end to give clearance for the two front steering wheels. The springs are of the semi-elliptical type, are long, and very flexible. Artillery pattern wheels are supplied, but in lieu of these detachable wire wheels may be had; personally I prefer the former and a Stepney wheel. 810×90 tyres are used for both the back and front wheels. Considering the weight of the car it would, I think, be cheaper in the long run if the 810×100 , which fit the same rims, were supplied.

I took the 15 h.p. car for an eighty-mile run, first through London traffic, which is a good test of an engine's flexibility, and the way the car could be slowed down and could pick up speed when a course through the stream of vehicles could be found was most delightful, and this nearly always on the direct (top) drive-merely a release of the throttle pedal, and without slipping the clutch, we had a crawl; the depression of the throttle pedal, and we had a dart forward. The change gear worked easily and the clutch was smooth, and picked up sweetly. On hills she behaved very well, doing Reigate and a nasty climb near Burford Bridge with five up and a heavy landaulette body on the second speed, which is certainly good for so loaded a 15-h.p. engine. The steering was easy and did not affect one's shoulder muscles even after a long drive, which has not been the writer's experience with some other makes of cars. The brakes were tested both on up and down gradients, and were found to be of ample power. As to the springing, luxurious is the only word for it. Personally I am in the habit of driving frequently in a single cylinder, short chassis, rather rapid, runabout, and the difference was immense. Altogether this latest production of Messrs. S. F. Edge, Limited, is an extremely pleasing vehicle, and one well fitted for the medical profession, either with a landaulette body for town use, or a two- or four-seated touring body for the country. The chassis price of the 15-h.p. is £350, and that of the 10-h.p. £250. Messrs. Edge must have great faith in their productions, for whereas most makers merely give a guarantee of six, or perhaps 12, months, they give one extending over three years from the date of delivery

A Point Worth Remembering.

Recently I was called professionally to see a street accident. A chauffeur had some difficulty in starting his car, and after lifting up the bonnet he flooded his carburettor, and then being in doubt as to whether his sparking plugs were all working, when the engine was running he shorted one with a screw-driver on to the frame; the result was that the petrol which had escaped when he flooded his carburettor exploded with the external spark he got when testing the plug. The moral, of course, is to be careful not to test the plugs if there is any petrol or petrol vapour about. Probably most motorists are aware of this danger, but the fact that a professional chauffeur learnt the lesson by a week's rest in a cottage hospital is my excuse for mentioning the point.

Oil-economisers.

In these days of buying oil in bulk, rather than in gallon cans, considerable saving of time and appearance of clothing may be effected by employing an oil-pump, by means of which the oil can be drawn from the cask and forced into a jug or convenient receptacle for handling. Recently while touring I noticed a neat form of pump for this purpose, which has been put on the market by a Warwickshire motor agent, but any pump with suitable pipe can be made to answer.

A Petrol Pourer.

With a great many of the cans in which petrol is sold there are difficulty, waste, and loss of time in getting the fluid into the tank. Messrs. Riches, of Store-street, London, have on sale what they call the perfect petrol pourer. It has various adapters, so that it can be fixed pretty well on any make of petrol can, is provided with a strainer, and as an air-tube is attached, it will be found a rapid and easy method of filling the petrol tank, especially if the latter is in an inaccessible position.

Good and Bad Cars.

De Dion Bouton, Limited, of 10, Great Marlborough-street, London, will be pleased to send to anyone interested. booklet contains a reprint of an article which was published in the Autocar under the title of "Good and Bad Cars," emphasises the difference, on more than one occasion brought out in these articles, between really good cars and more or less indifferent ones. Both classes of car may be of good value, probably, for the money asked, but the lower priced chassis will not, as its novice owner fondly believes, be as good as the one which may cost, say, £100 more. cheaper car may go as well at first as the other, but, as this brochure points out, after 5000 miles the more expensive one will need much less repair. In other words, this pamphlet professes to show that first-class cars are the cheapest in the end and that inferior cars are unreliable and unsatisfactory.

THE OPENING OF THE LONDON MEDICAL SCHOOLS.

Charing Cross Hespital Medical School.—The session opened on Oct. 4th, when Sir T. Clifford Allbutt presented the prizes. The Dean, Mr. F. C. Wallis, in his report made the following interesting remarks concerning a "London degree for London students":—"With regard to the new Royal Commission on the London University a letter, signed by all the medical schools, was sent to the Prime Minister in the sense of the following resolution:

That the Royal Commission, which the Senate of the London University has requested the Government to appoint, should be allowed to take evidence as to the means by which the medical degrees of the University might be made more accessible to London students.

This is a matter of grave, even vital, interest to the existence of the London medical schools, and I am quite sure if the public only could appreciate what it means a lively and profitable interest in this most important matter would be taken. At any other teaching school in the United Kingdom, outside this metropolis, any student can obtain a doctor's degree for the same amount of time and money that it takes the London student to get the double qualification, which, although an excellent one, does not carry with it the allimportant title of 'doctor.' It may be said that it does not matter what a man's qualifications are if the man himself is good. But this is not true in practice, especially when a man is starting his career. In common with many others, I have received various letters from former students complaining bitterly of the fact that they are surrounded by men with doctor's qualifications obtained at either a provincial, Scotch, or Irish University, at no greater trouble and expense than it has taken the London man to obtain his double qualification, and, moreover, it has actually occurred that in advertising for candidates for posts at small provincial hospitals it has been stated that a doctor's degree is essential, thus effectively barring the London man with the double qualification. There is no doubt that the absolute medical examinations themselves for the London M.D. degree do not present any unusual difficulties to the ordinary examinee. The whole trouble lies with the matriculation examination, concerning which I could say much, but this is not the time or place to do so. The fact, however, is known to all of us, and will, I hope, be dealt with by the proper people when the evidence is taken at the Royal Commission. Now the practical result of all this, as it at present stands, is that our old students say, and one cannot blame them, that, much as they like their old school, and although they know of the many advantages in other ways which a student gets in London, still this stumbling block of a doctor's degree is so great that they neither send their own sons nor those of their friends to London, but recommend them to some provincial school where the facilities for obtaining a doctor's degree are made as easy as they are made impossible here in London. I say made impossible in London, for I am afraid that is what has been going on for years with regard to the London University, which, in this matter, has been held in subjection by a small body of men whom one would credit with larger minds and greater foresight than they seem to possess. Instead of such being the case, with a narrow and selfish outlook they cling to all the old difficulties of the London Some matters worthy the consideration of all car purchasers are dealt with in a little booklet which Messrs. rapidly ruining London as a teaching medical centre.

And thus all the splendid wealth of chinical material, all the facilities of obtaining the best medical education in the world, are being lost, ruined, and thrown away, because of the selfishness of a few and the apathy of the many. These things have been frequently written about in the medical press, but it is vitally necessary for the public to take up this matter and to do their best to protect their own interests by helping the medical schools of London to have the power to offer to the London medical student a degree which can be obtained with equal facility to any of the other degrees already mentioned. By this, and this alone, will London regain her lost position as the best medical school in the world." As regards the work of the school Mr. Wallis said: "Various changes have been made in the teaching in the surgery department, and a new departure has been made in the method of teaching surgery which I think will be most successful and will probably be adopted by other schools. It has been obvious for some time that the old method of imparting knowledge by a set of stereotyped lectures is ineffective, and that having regard to all that a student has to do in these days the less lectures of the old-fashioned type he has to attend the better, as he will have so much more time to give to clinical and other work which is of the first importance. Without wearying you with the details of the scheme, the practical result is that the minimum number of lectures will be given on the principles and practice of aurgery and much more clinical surgery will be taught. As regards medicine, there have not been any particular changes in the method of teaching, and, indeed, it would seem as though none were required, as in the last examination 100 r cent. of the candidates from Charing Cross passed in this subject." Sir T. Clifford Allbutt delivered an address which we report on another page. In the evening a dinner of the past and present students of the hospital was held under the chairmanship of Dr. William Hunter. 100 were present, the principal guest being Sir Clifford **▲llbatt.**

King's College Hespital.-No opening ceremony was held at the College, but the annual dinner of the past and present students took place at the Waldorf Hotel on Oct. 1st, Mr. T. Hugh Smith, of Farningham, being in the chair. Of the hospital consulting and active staff the following were present: Dr. I. Burney Yeo, Dr. D. Ferrier, Professor W. Rose, Sir W. Watson Cheyne, Mr. A. B. Barrow, Dr. N. Dalton, Mr. A. Carless, Dr. Urban Pritchard, Dr. J. F. W. Silk, Dr. John Phillips, Dr. A. Whitfield, Dr. H. J. M. Playfair, Dr. G. B. Flux, Dr. R. H. Steen, Dr. J. C. Briscoe, Mr. F. F. Burghard, Mr. C. E. Wallis, and Mr. V. Cargill. Amongst the others present were Dr. J. Walters, Dr. C. H. Allfrey, Dr. S. Short, Dr. P. Lewis, Dr. G. E. Shuttleworth, Dr. C. P. Childe, Dr. W. J. Essery, Dr. E. Wood, Mr. Val. Matthews, Dr. J. Davidson, Dr. E. Thurston, C.I.E., and the secretaries, Dr. StClair Thomson, Mr. Peyton Beale, Dean of the School, and Dr. H. W. Wiltshire. There were 106 present. Mr. Smith proposed the toast of the evening, and in his remarks pointed out the immense amount of work which the student of the present day had to carry out in comparison with the student of past times, and also how much more strenuous his career had become. He also alluded to the fact that this was the first year of the school's existence as the Medical School of King's College Hospital. Previously it had been part of the Medical Faculty of King's College, London, but owing to the incorporation of that body with the University of London the medical school of the hospital, though still a school of the University, became independent. This was also necessary in view of the impending removal of the hospital to South London. He also alluded to the excellent examination results of the last few years. Dr. Walters, in replying, said that he was a student in the year 1853, and he gave some idea of the work of the hospital and its staff at that time, mentioning the names of Farre, Todd, and Partridge as great teachers He said that he had no doubt whatever when the hospital was rebuilt at Camberwell and was able to expand its special departments, which were at present hopelessly cramped, its work would be better than it had ever been, and would come to occupy a premier position amongst London hospitals and medical schools. Thanks were returned to the committee and secretaries of the dinner, which was voted a great success by all present.

London Hospital Medical College. - The opening of the ssion was marked by a staff reception of old students in the library of the College on Oct. 1st. In the evening the annual dinner was held at the Savoy Hotel. Dr. F. J. Smith presided and was supported by Dr. Percy Kidd, Dr. A. H. N. Lewers, Dr. H. Russell Andrews, Mr. C. W. Mansell Moullin, Mr. E. Hurry Fenwick, Mr. T. H. Openshaw, Mr. Roxburgh, and other members of the London Hospital staff. A large The occasion company of old London men were present. marked several new departures: the usual musical accompaniment was conspicuous by its absence, as was the common long list of toasts and speeches, both welcome omissions, judging from the evident enjoyment of all who attended. After the usual loyal toasts had been given from the chair, Dr. Smith made the one and only speech, the "London Hospital." Having read various letters of apology from those prevented from attending, including one from the Hon. Sydney Holland, and another from an old student who had attended on these occasions for 54 years and now on account of failing eyesight was unable to do so, he referred to the losses which the hospital had sustained by the death of two of its most promising young members of the staff, and to the fact that Mr. Mansell Moullin was shortly joining the consulting staff. After a few words congratulating Sir Jonathan Hutchinson on his recent honour, Dr. Smith drew attention to the continued need for money to further medical education, so as to enable men to undertake research work, which they could not do if they had to earn their own living. Mention was made of the London Hospital Medical Club and its need, now that it was a medical benevolent institution, for support. There is no annual subscription, merely an entrance fee of £1, and during the year it has been the means of affording relief to various necessitous cases. Dr. Smith concluded his humorous speech by advising all "to play at musical chairs" and to walk round and renew old friendships.

Middlesex Hospital.—The seventy-fifth winter session of the Middlesex Hospital was opened on Oct. 1st by Lieutenant E. H. Shackleton, C.V.O., and Mrs. Shackleton. They were received in the board room of the hospital by members of the weekly board of governors and the honorary staff of the hospital. A guard of honour com-posed of the Middlesex Hospital Cadets of the University of London Officers' Training Corps was drawn up in the hospital garden. A large marquée erected over the tennis-court was filled to overflowing with the past and present students, the nurses and their friends, to the number of over 1000. introductory address was delivered by Dr. J. Strickland Goodall on "Walking the Hospital" (see p. 1061). After the Dean, Dr. H. Campbell Thomson, had read his report for the past year Lieutenant Shackleton presented the prizes to the students and Mrs. Shackleton gave the Fardon Memorial medals to the nurses. Lieutenant Shackleton in a brief speech alluded to the medical department of his own expedition. He said they had three doctors with them, and they had come through without any deaths owing to their help. One man lost an eye, and for the purposes of the operation he had been stretched on a board among the ice. Another man lost a toe through frost-bite, and he still carried the toe about with him as a trophy. He mentioned the strange observation that in these extremely cold regions the rotifers were able to live and to multiply, and that observations on them since had shown that they continued to do so through very wide ranges of temperature. regard to the temperatures of the members of the expedition, he stated that they suffered some ourious changes. On the plateau they were often down to 93° or 94° F., but they became normal again after meals. It had been said that people never caught a cold in the Polar regions, and the members of his expedition did not do so until they opened a bale of clothing which had been packed up in England. The germs were there and they caught. but the cold disappeared when they went out, while those remaining in the hut continued to suffer. He and Mrs. Shackleton appreciated the welcome they had received, and he mentioned the Nimrod Exhibition which he hoped they would visit as the proceeds were to be given to charities. Lord Cheylesmore, chairman of the weekly board, proposed a vote of thanks to Dr. Goodall and to Lieutenant and Mrs. Shackleton. Prince Frances of Teck, who seconded, also entreated those present to go and see the Nimrod Exhibition, for part of the proceeds were to go to that hospital. He congratulated Lieutemant Shackleton on

returning safe and sound to this country and also upon his having chosen the South Pole instead of other places so that he had returned not only with honour but in peace. The annual dinner was held at the Empire Hall, Trocadero Restaurant, on the same evening, Mr. John Murray being in the chair. A large number of old stadents were present, and several members of the lay board, including H.S.H. Prince Francis of Teck, Lord Cheylesmore, Mr. W. E. Gillett, chairman of the school council, Mr. Charles Davis, and Mr. Felix Davis, the total number present being ower 170. After the usual loyal toasts had been honoured the Chairman proposed the toast of "Success to the Middlesex Hospital and Medical School." referred to the air of vitality and activity which characterised the school, and alluded to the interest taken by the students in Mr. Haldane's Officers' Training Corps, to which they contributed 30 cadets. He also described the recent negotiations, now practically concluded, to secure jointly with St. Mary's Hospital a permanent athletic ground, and mentioned the recent generous donation from Mr. J. Bland Sutton of £1000 to the fund for this purpose. Lord Cheylesmore, chairman of the weekly board, replied on behalf of the hospital. Dr. H. Campbell Thomson, the dean, replied on behalf of the school. He referred to the establishment of a special schoolarship for students from New Zealand and announced that the outlook as regards entries at the school was even better than that of last year. Mr. Thomas Carwardine of Bristol replied on behalf of the old students, and Mr. H. G. Kilner, the senior Broderip scholar, on behalf of the present. The toast of "The Visitors" was proposed by Mr. Andrew Clark and responded to by Chevalier Wilhelm Ganz, who has for more than 42 years assisted at these dinners. The health of "The Chairman" was proposed by Mr. Bland-Sutton, and in his reply Mr. Murray expressed his gratification at the reception accorded him. The proceedings throughout were marked by great enthusiaem, and the frequent references to the growing prosperity of the school and to its increasing numbers were received with acclamation. In particular, allusions to the kenerous donation made by Mr. Bland-Sutton to the athletic ground fund, and to the untiring energy of the chairman in looking for a suitable ground, were accorded a werm reception, especially by the present students, who were present in considerable numbers and contributed in no small degree to the general enthusiasm and to the success of the evening. In response to general demands the healths of Prince Francis of Teck, Mr. Bland-Sutton, and the resident medical officer, Mr. A. E. Johnson, were informally toasted. An excellent musical programme was arranged by Chevalier Ganz, assisted by Mr. M. Sterling Mackinlay and Mr.

St. George's Hospital Medical School .- The opening ceremony was held on Oct. 1st, when Dr. H. D. Rolleston delivered an address on "St. George's and the Progress of Physic," which we published in our last issue. The annual students' dinner was held on the same evening at Prince's Restaurant, under the chairmanship of Mr. A. Marmaduke Sheild, consulting surgeon to the hospital, and proved a very successful function. A large gathering of old students was present, representing entries that in an appreciable number of cases must have been as much as 40 years apart. Mr. Sheild, whose presence among his old friends after his long and trying illness was welcomed by them with the greatest possible enthusiasm, achieved the difficult task of making a sympathetic, witty, and new speech in proposing the Royal toasts. Captain St. Leger Glyn proposed the toast of "St. George's Hospital Medical School," in reply to which the Dean, Dr. E. Ivens Spriggs, was able to report a continuance of the movement upward in the schools, and to lay upon the table an imposing list of honours and appointments gained by St. George's men during the year. Both these speeches were of good cheer for the future, while both showed the difficulties and anxieties which the authorities of the hospital, lay and medical, fiscal and educational, have had to surmount. Squire Sprigge proposed the health of Dr. Rolleston Square sprigge proposed the neath of Dr. Rolleston is the character of the orator of the day. Dr. Arthur Latham proposed the toast of "The Past and Present Students of St. George's Hospital," which was session was marked by the annual old students dinner which took place at the Hotel Cecil on Oct. 1st. Mr. adequately responded to by Dr. C. D. B. Hale and Mr. J. B. Lawford was in the chair, and the company of the assembly in his speech proposing Mr. Sheild's health, Surgeon-General W. L. Gubbins, A.M.S., Mr. C. T.

in which he expressed the great pleasure it was to St. George's men to see among them again their brilliant and popular surgeon, so long laid aside by illness incurred in the discharge of his hospital duties. Mr. Sheild's brief reply brought a very successful dinner to a conclusion.

St. Mary's Hospital Medical School.-The session was opened on Oct. 1st by the distribution of prizes which was performed by Dr. H. A. Miers, Principal of the University of London, who delivered subsequently an address on "Theories." In the evening the annual dinner of past and present students was held at the Café Royal, where over 130 past and present students assembled and spent a very pleasant evening, the enjoyment of which was heightened by the unusual brevity of the speeches and the uncanny behaviour of that caustic magician Dr. Byrd-Page. Dr. Milner M. Moore, who occupied the chair, in proposing the toast of his old hospital and medical school, recalled the fact that he was one of the oldest of St. Mary's students, since he passed his hospital days in the early "sixties," a confessionin which it was difficult to believe. The toast was replied to-by Mr. H. A. Harben, chairman of the hospital board, and Mr. W. H. Clayton-Greene, Dean of the Medical School. Mr. Harben alluded to the harmonious relations existing between the hospital and the school and the desirability of the present arrangements which allowed the teachers of the preliminary sciences to keep in close touch with the clinical work of the hospital. Whilst he rejoiced at the recent opening of the Clarence wing for 31 patients under therapeutic inoculation, he referred to the not far distant prospect of a State or municipal subsidy of the voluntary hospitals. The Dean outlined in a quick and lucid speech the recent progress of the school. He was able to announce a satisfactory entry for the coming session and an excellent record of achievement in the past year. The most notable success was gained at the last examination for the Fellowship of the Royal College of Surgeons of England, when five men went up and were all successful. The Henriques operating theatre had been in use for a year and the fund which had been raised by the students for the permanent endowment of a cot had attained its object. Probably the most important feature of the year from thepoint of view of the school's future was the successful issueof the negotiations to purchase an athletic ground at Park Royal in conjunction with Middlesex Hospital; the desirability of this arrangement was guaranteed by the happy relations which had existed between the two schools during their joint tenancy of a ground at Wormwood Scrubbs for the past four years. The schoolwas in the enjoyment of a prosperity somewhat remarkable in relation to the size of its hospital, and its future might be faced with considerable hope and confidence. Clayton-Greene expressed his warm thanks to Mr. Harben for his continual devotion to the interests of the medical school, and to Mr. B. E. Matthews, the secretary, who put such good work into its administra-tion, and finally he alluded in sympathetic terms to the illness of Dr. H. A. Caley, his predecessor, who had laboured unsparingly in reorganising the school during the most critical period of its existence and to whom its present state was so largely due. He hoped that before long St. Mary's would welcome Dr. Caley back to his work again, a wish warmly endorsed by his audience. The "Health of the Visitors" was proposed by Mr. J. E. Lane in a witty little speech, and responded to by Dr. H. A. Miers, the "opening lecturer" of the afternoon, who said that such a gathering was encouraging to him, since it showed him the real existence of a collegiate life in the University of which he was principal. He also alluded to the recent renewal of negotiations between the Royal Colleges and the University in the endeavour to make the London degree more accessible to all London medical students. The last toast, that of the Chairman, was given by Dr. Sidney P. Phillips, and after Dr. Milner Moore's response the gathering split itself up into groups of contemporaries who were not silent concerning old times at St. Mary's.

Harris, J.P., the Rev. A. O. Hayes, Mr. J. A. Jennings, Professor W. Osler, Dr. J. Priestley, Mr. G. Rendle, Mr. G. Q. Roberts, Mr. G. S. Saunders, and Colonel D. Wardrop, A.M.S. After the usual Royal toasts, the chairman, in proposing "St. Thomas's Hospital and Medical School," referred sympathetically to the absence, owing to illness, of Mr. Wainwright (the treasurer) and Mr. H. H. Clutton (the senior surgeon). He also deplored the untimely death of our late editor, Thomas Wakley, a distinguished St. Thomas's man, who was in the chair at last year's dinner. The toast was responded to by Mr. C. T. Harris (almoner to the hospital) and by Mr. Cuthbert S. Wallace (Dean of the Medical School). Mr. Harris congratulated the hospital on the opening of the new female medical ward, amongst other improvements, and on the near prospects of the opening of the new maternity ward. He also hinted at the possibility of further improvements in the out-patient department. Mr. Wallace, in a short but racy speech, recounted the numerous successes of the hospital year, both academic and athletic. The last toast of the evening was that of "The Chairman," proposed eloquently by Dr. H. R. Hutton and Chairman," proposed eloquently by Dr. H. R. Hutton and received with acclamation. In the course of the evening Mr. Barclay Gammon gave a humorous sketch, which was highly appreciated.

University College Hespital and Medical School.—The session was opened on Oct. 1st, when Sir John Tweedy delivered an introductory address (see p. 1060). In the evening the annual dinner of the old and present students was held at the Gaiety Restaurant, Strand. Mr. A. Pearce Gould, senior surgeon of the Middlesex Hospital, occupied the chair. 126 diners were present. After the toast of "The King," Mr. A. E. Barker, senior surgeon of the hospital, proposed the toast of "The Navy, Army, and Auxiliary Forces," to which Major C. G. Spencer, R.A.M.C., professor of military surgery at the Royal Army Medical College, responded. Major Spencer, in his speech, gave a short but very interesting outline of the scheme with regard to the Special Reserve service. At the beginning of his speech, in which he proposed the toast of "The University College Hospital and Medical School," Mr. Pearce Gould referred in touching terms to the recent sad death of Dr. Radcliffe Crocker, for many years physician in charge of the skin department at the hospital. His remarks, which were full of reminiscences of his old school and teachers, were listened to with rapt attention. Dr. H. Batty Shaw, Dean of the medical school, replied in suitable terms. The toast of "The Chairman" was proposed by Sir Thomas Barlow, senior physician of the hospital.

Other Hospitals.—At St. Bartholomew's Hospital and the Westminster Hospital Medical Schools, although the usual annual dinners of past and present students were held, there were no opening addresses nor other formal inaugural proceedings of the school session.

INFANTILE MORTALITY IN ALEXANDRIA.1

An exceedingly interesting and instructive report on infantile mortality in Alexandria has recently been presented to the municipality by Mr. E. G. Carpenter, medical officer of health of the city. The first paragraph of the report is calculated to convince one of the necessity for such an investigation and to bring home to the most sceptical the appalling waste of infant life in one of the most Europeanised towns of Egypt. We read that " between January 1st, 1902, and December 31st, 1907, 83,404 children were born, and of this number 24,948 died," or, as Mr. Carpenter aptly puts it in the original French, "were moved down [fauchés] in their first year of life." These figures represent a mortality of 30 per cent., and an instructive comparison is made with statistics of other countries on the same subject. For this purpose the several years are examined in detail, and it is found that the average mortality for the six years is 288 per 1000 births. This figure is only exceeded by Chili with 326. Then follow Russia with 268, Austria with 224, Roumania with 218, England 150, Scotland 126, Ireland 103, down to New Zealand, which has the

best record with 79. Further, as compared with some of the larger cities in England, Alexandria with her 288 compares very unfavourably with London 141, Manchester 177, Birmingham 184, and even with Preston 244 and Blackburn 207. The two last named are notorious for their infantile mortality, due, it is said, to the large number of women employed in the cotton mills. Similarly, the poorest quarters of London show a better average than Alexandra; thus Whitechapel is 123. Mile End 126, St. George 141, and Limehouse 168.

Turning now to the period of infancy in which death occurs, tables are given showing in detail the mortality in the first month, between the first and the third month, between the third and the sixth month, and between six and 12 months. It has been noted that there is a severe mortality in the first month, with a decrease in numbers between the first and third month, and after that a further increase. Comparatively again, in 1904, for every 1000 births, 29 died in the first month in New Zealand, as against 78 in Alexandria; and, in the period from six to 12 months, whereas only 14 died in New Zealand, the mortality in Alexandria amounted to 129. This figure does not vary appreciably in the different years under review, and approximately 40 per cent. of the deaths occurred before three months, 20 per cent. between three and six months, and 40 per cent, between six and 12 months. In January the deaths under one month are high in comparison and those between six and 12 months are low, but in July exactly the contrary is the case. The death-rate of infants under one month steadily diminishes from January to July and then progressively increases to the end of the year, while the mortality between six and 12 months increases from January to July and then diminishes month by month. deaths between one and three months remain almost stationary throughout the year, but tend to follow the same variations as those under one month, and those between three and six months more closely follow the curves of the period between six and 12 months. Taking the totals of the six years, 10.6 per cent. died in January and 5.15 per cent. in June, the birth-rate at the same time being respectively 9.77 per cent. and 6.75 per cent.

Putting the results in the form of curves, it appears that the curves of births, still-borns, and deaths below one month are identical; but there is a diminution of the curve in the middle of the first year and an increase towards the end. This is natural, as the birth-rate increases and there is more likelihood of still-born or premature births. In England the births are more or less evenly distributed throughout the year, with a slight increase in June and July; but in Alexandria more children are born in November, December, and January than in any of the other months, and fewest of all in May, June, and July-a curious fact for which Mr. Carpenter cannot offer any explanation. The proportion of still-births is 4.15 per cent., as compared with 4 per cent in England. The curves for the periods from three to six months and from six to 12 months show an appreciable increase during the summer months, attaining their maxima in July, owing to the prevalence of diarrhoea. A similar rise occurs between the first and third year of life. Taking a total of 21,852 deaths under ten years, 11,483 were boys and 10,369 were girls, being in the proportion of 1.10 to 1.

Coming now to the diseases contributing to this excessive mortality, Mr. Carpenter gives further lengthy tables which bring him to the conclusions that the majority of deaths are due to (1) prematurity, lack of development, and marasmus; (2) diarrhœa of various forms; and (3) bronchitis and pneumonia, especially the two former. Of 12,653 deaths during 1905-07, 10,899 were due to these three causes. Comparing the general causes of mortality with English figures for the same period, Alexandria stands fairly well, and has also only one-third as much tuberculosis as England; but, on the other hand, there is three times as much mortality from diarrhoea, twice as much from marasmus, three times as much from rachitic diseases, and twice as much from bronchitis. In the three years in question, of a total of 7994 deaths 3892 were due to diarrhœa. Mr. Carpenter ascribes the mortality arising from prematurity, feeble development, and marasmus to ignorance and neglect of the hygiene of pregnancy on the part of the mother. The bad effects of this neglect as a factor in infantile mortality are particularly noticeable in the first month of life, diarrhea becoming more prominent as a cause in the later months. Mr. Carpenter finally recommends

¹ Rapport sur la Mortalite Infantile. Addressed to Professor Gotschiich, sanitary inspector of the municipality of Alexandria, by E. G. Carpenter, D.P.H. Cantab., F.R.C.S. Eng. Société de Publications Égyptiennes, Alexandria. 1909.

the establishment of a maternity home and a stricter supervision of midwives, by whom almost every native woman is attended, and the appointment of lady health visitors, who shall be qualified midwives, specially trained in the principles of infant feeding and general management of infants, whose duties shall be to visit each lying-in mother and give such advice on these matters as may be necessary. He considers that the cause of the diarrhea is contamination of the food, either by flies or dust, and recommends the establishment of gouttes de lait throughout the town for the supply of good and clean milk, as well as certain improvements in the sanitary administration of the town generally.

The report is a very valuable statistical record and must have entailed an enormous amount of work. Many will hold that Mr. Carpenter's recommendations for the prevention of this awful mortality are not practical measures, taking into consideration the people with whom he has to deal. It is the old story of the Ethiopian who cannot (and will not) change his skin (or his customs engrained in him for centuries). The absolutely filthy habits, both personal and domestic, of the lower class native, and their colossal ignorance of, and indifference to, all matters hygienic and sanitary, render reasonable recommendations for their improvement nearly futile; while their deep-rooted objection to soliciting medical help till the case is in extremis makes the question of their salvation even more difficult. has to be remembered, for it is true that so long as "Kismet" ("It is the will of God") continues to be the solace for all earthly sorrow or disappointment of any kind, our crusade against the awful waste of infant life in Egypt will be altogether unavailing. But vigorous endeavour will in the end, it is to be hoped, lead to good result.

Looking Back.

PROM

THE LANCET, SATURDAY, Oct. 8th, 1881.

The mass of the middle classes of society has begun a reat movement in the acquisition of knowledge, in the discovery of rights, in the conviction of absurdities, and in virtue and liberality of sentiment. The higher orders see the impossibility of arresting this progress, and titles and decorations will no longer command even notice unless supported by real excellence. Among the higher ranks are some who, so far from viewing this movement of other ranks with dread, step forward to promote it, and the share taken by some of exalted rank and office in the founda-tion of this University demonstrates a liberality and generosity which will ever do honour to England, and which are worthy of all imitation. So ought physicians to act towards the general practitioner, to make every effort to improve his general education and his professional knowledge. In fact, all those who lecture or practise at public institutions act, whether they will or not, contrary to the narrow views of interest. For they are occupied in imparting knowledge to the rising generation of general practitioners; occupied in making them as learned as themselves. In me such narrow views would be the height of baseness and ingratitude; for I hesitate not to avow,—I rejoice in this public opportunity of declaring, that to the general practitioners of England, Scotland, and Ireland, I am indebted for my professional success. When I commenced my professional career, I determined upon trusting for success to working hard, and to conducting myself as well as the infirmity of human nature would allow. I determined, however long I might wait for success, never to fawn upon and run after my superiors, nor to stoop meanly to my inferiors; never to intrigue for an advantage, nor to employ trumpery artifices for making myself known to the public. For many years I toiled and saw many of my contemporaries, nay of my juniors, who worked less but were wiser in their generation, pass by me. I published work after work, edition after edition, and paper after paper was honoured with a place in the Transactions of the first medical society in Europe: I was physician to a large metropolitan hospital, and had attended there and gratuitously out of doors above 20,000 patients. But in vain. In 1828, my profession was no more

lucrative to me, was as short of my actual expenses as it had been in 1818. At that time THE LANCET was pleased, now and then, to publish a clinical lecture delivered by me at St. Thomas's, and my practice at once doubled. The following year it published the greater part as I delivered them, and my practice doubled again. Last season THE LANCET published them all, and my practice was doubled a third time. This astonished me the more, as my clinical lectures were generally delivered with little or no premeditation, while all I published myself had cost me great labour, many a headach, and much midnight oil. It was through the general practitioners in the large majority of instances, and through general practitioners for the most part with whom I had not the honour of any acquaintance, that the publication of those lectures accomplished my success. To the body of general practitioners, therefore, I owe a debt of gratitude. They have called me forth spontaneously, from no interested motive, and I cannot exert myself too much in the education of their successors.

Public Bealth.

REPORTS OF INSPECTORS OF THE MEDICAL DEPARTMENT OF THE LOCAL GOVERNMENT BOARD.

On the Appointment of the Medical Officer of Health and on the Sanitary Circumstances and Administration of Gravesend, by Dr. R. J. REECE.2—The old borough of Gravesend, which in 1851 had a population of 16,600, has now about 30,000 inhabitants, of whom a small portion live on the water and some 800 in the garrison and fort. The population consists to a large extent of pilots, seamen, and bargemen, together with dock labourers who work on the opposite side of the Thames at Tilbury. There appears to be an adequate supply of working-class dwellings, and of a total of 6067 houses in the borough some 60 per cent. are rated under £15 per annum. The sanitary history of Gravesend has been well recorded in previous reports to the Local Government Board, notably by Mr. Netten Radcliffe in 1877 and by Sir Shirley Murphy in 1885, and is now brought to date in a comprehensive report by Dr. Reece. This report, like its predecessors, lays stress upon the various disadvantages, from a sanitary point of view, which result from the cesspool system. Gravesend is one of the few large towns remaining in England where practically every house has its cesspool and where new cesspools are dug as new dwellings are erected. Many years ago a material proportion of the houses obtained water from wells sunk into the chalk by the side of the cesspools, but in more recent times all these wells have been disused, or in some cases have been themselves turned into cesspool overflows. The water of the town is supplied by the Gravesend and Milton Waterworks Company from wells sunk into the chalk at Windmill Hill, the highest point in the borough. In these wells water is reached at a depth of 114 feet from the surface, and the supply is augmented by various lateral adits which have been driven at the bottom of the wells. Judged from chemical analysis the water is of high organic purity, but in view of the extensive contamination of the chalk in the neighbourhood the underground water which reaches these wells cannot be regarded as free from risk. On this view Dr. Reece speaks with approval of the present intention of the company to construct new wells about three miles from the borough. Calculating from the daily consumption of water per head, and allowing for the fact that rain from roofs gains access to many of the cesspools, Dr. Reece estimates that a total of over 220,000,000 gallons of sewage reaches these receptacles each year. From local data regarding the emptying of cesspools, however, it appears that only some three or four million gallons are annually removed by pumping and scavenging; the balance must find its way into the Thames or remain in the chalk to the danger of the wells of the water company. These considerations are, of course, not the only or the most obvious of the sanitary

¹ Excerpt from Introductory Address to a Course of Lectures on The Principles and Practice of Medicine by Professor Elliotson, M.D., delivered at the University of London, on Wednesday, Oct. 5th, 1831.

1098 THE LANCEY,]

objections to the system, and on review of the circumstances generally the report strongly recommends the abolition of the cosspools and the substitution of an efficient system of sewers in those parts of the town which are at present unsewered. The present sewers, which convey mainly surface water but also receive the discharges from some house drains and waterchosets, have an outfall into the river. Adherence to the cesspool system has not saved the Gravesend authorities from difficulties in regard to sewage disposal, and an appeal is now pending to the High Court in an action taken by the Thames Conservancy against the town council for polluting the Thames. Among other points to which the report directs attention is the need for closing various insanitary dwellings and demolishing those which are incapable of repair; the state of the slaughter-houses, not one of which, "either from position, construction, or condition, is fit for the slaughtering of animals for the food of man"; and the need for improvements in arrangements for dealing with cases of infectious disease. The most pressing need of the town appears to be that of securing the services of a medical officer of health who is free from the trammels of private practice and who will be responsible for the direction of the work of the sanitary staff. The latter needs strengthening by the appointment of an additional inspector whose qualifications should include experience in food inspection. A good opportunity of making the desired reform will shortly be afforded, as the present medical officer of health of Gravesend is about to retire from the office, and the appointments for the neighbouring areas of Northfleet and Strood are due for reconsideration by the local authorities concerned. By combined action in these districts the appointment of a medical officer of health to give his whole time to public duties could readily be secured. In the neighbourhood of Gravesend a practical example of the advantage of this course is to be found in the Milton combination, which some years ago was in similar circumstances effected, at the instance of the Local Government Board, for the purpose of the joint appointment of a medical officer of health

ANNUAL REPORTS OF MEDICAL OFFICERS OF HEALTH.

Report on the Health of Belfast for 1908 .- Mr. H. W. Bailie, superintendent medical officer of health of Belfast, has just issued his report on the health of the city of Belfast for 1908, the main facts of which may be summarised as regards figures as follows: The area of the city is 16,504 acres, the population 380,344, and the density 25.8 persons to an acre. The birth-rate was 29.7 per 1000 and the total mortality 19.5 per 1000. The infantile death-rate was 147 per 1000, the zymotic 1.8, and the phthisis death-rate 2.3 per 1000. The number of cases of infectious diseases notified was 3.6 per 1000 of the estimated population, which is less than in 1907, and much less than the average for the ten years 1898— The death-rate is 1.8 below that of 1907 and 1.7 1907. below the average of the previous ten years; that is, a saving of 684 lives as compared with 1907. Although the zymotic death-rate is higher than in 1907, there is a reduction in mortality from each of the principal zymotic diseases as compared with 1907, except typhus fever, pertussis, and diarrhea. 82 fewer cases of enterio fever were notified than in 1907. It is interesting to read that while there has been a slight fall in the birth-rate in Belfast for several years, it has not been so marked as in many of the great cities of Great Britain, the average rate for the 76 great towns of England and Wales having fallen to 27.0 per 1000. The rate in Belfast for 1908 (29.7) is the lowest ever recorded for the city, the average rate for the 10 years ended 1908 being 31 · 1. Of the total deaths—7523 there were 1258 from tuberculous diseases (880 from phthisis and 378 from other forms of tuberculosis), 1210 from diseases of the respiratory system (exclusive of pneumonia), 753 from pneumonia, 281 from cancer, 260 from diarrheea, 186 from measles, and 137 from whooping-cough. There were only 57 deaths from typhoid fever, 33 from diphtheria, 10 from typhus fever, and four from scarlet fever. It is a remarkable fact that while the deaths from scarlet fever, diphtheria, typhoid fever, phthisis, and other forms of tuberculosis were less in 1908 than in 1907, there was an excess in diarrhoea, pneumonia, diseases of the respiratory organs (exclusive of pneumonia), and cancer. Indeed, during the last three years malignant disease is steadily increasing. It is a most deplorable fact-rendering this report in many respects useless-

that while the causes of 4356 deaths are briefly reviewed, "the causes of the remaining 3167 deaths, with the exception of 66 due to cerebro-spiral meningitis, are not accounted for, nor is there any means at my disposal for obtaining these necessary details, and there is no official method for obtaining the name, address, or nature of the filness which caused the death of any individual during the past year" (p. 23 of the report). This lamentable state of affairs, so strongly animadverted upon by the Belfast Health Commission and so frequently pointed out by the late medical superintendent in his reports, still continues. Every excuse is put forward by the corporation for such a culpable state of ignorance of the very A.B.C. of public health but the real one, which is the fact that by promoting a Parliamentary Bill on the question they could have made matters right at any time during the past ten years. In reference to infantile mortality (147 per 1000 births) there is plenty of work to be still done, but it is regrettable to read that "the difficulty of analysing closely the causes of the excessive infantile mortality-rate is rendered impossible by the exceptional circumstances existing in Irish cities, that is, that the medical officer of health does not receive returns showing the number of deaths, with addresses and causes, whereas in English and Scotch cities these returns are made weekly (p. 89 of the report). It is satisfactory to record that the very high death-rate from infantile mortality in 1908 is diminishing in 1909 so far, but we know the cause largely from returns of the registrar of city cemeteries (pp. 92 and 93 of the report), and generalisations based mainly on such statistics alone do not give the scientific accuracy that is needed to adopt preventive measures. The details in the report as to national schools show that marked improvements have been effected in their sanitary condition. The report contains a great deal of interesting information, but is sadly vitiated by the want of knowledge of the causes of death in so many instances, a state of affairs for which the medical officer of health is not responsible; but it is a disgraceful condition of matters that in a great city like Belfast, with a population of 380,344, out of 7523 deaths occurring in 1908 the causes of 3167 (with the exception of 66 due to cerebro-spinal meningitis) are not accounted for, while the medical officer of health has no means at his disposal for obtaining these details.

VITAL STATISTICS.

HBALTH OF BNGLISH TOWNS.

In 76 of the largest English towns 7626 births and 3879 deaths were registered during the week ending Oct. 2nd. The annual rate of mortality in these towns, which had been equal to 13.0 and 12.6 per 1000 in the two preceding weeks, further declined to 12.3 in the week under notice, and was lower than in any week since the middle of August. During the 13 weeks of the past quarter the annual deathrate in these towns averaged only 11.9 per 1000, and in London during the same period the rate did not exceed 11.4 per 1000. The lowest annual rates of mortality recorded in the 76 towns last week were 4.9 in Hornsey, 5.6 in Rotherham, 6.5 in Willesden, and 6.9 in Walthamstow; the rates in the other towns ranged upwards, however, to 17.6 in Great Yarmouth, 18.7 in Huddersfield, 19.1 in Burnley, and 20.0 in Oldham. In London the recorded death-rate last week did not exceed 11.6 per 1000. The 3879 deaths in the 76 towns last week showed a further decline of 94 from the numbers returned in the two preceding weeks, and included 431 which were referred to the principal epidemic diseases, which were referred to the principal epidemic diseases, against numbers declining steadily from 849 to 509 in the five preceding weeks; of these 431 deaths, 263 resulted from diarrhoea, 55 from whooping-cough, 43 from diphtheria, 32 from scarlet fever, 21 from "fever" (principally enteric), and 17 from measles, but not one from small-pox. The 431 deaths from these epidemic diseases last week were equal to an annual rate of 1.4 per 1000, a lower rate than in any week since the middle of August. No death from any of these epidemic diseases was registered last week in Kast Ham, Hornsey, Aston Manor, West Hartlepool, or in five other smaller towns; the annual death-rates therefrom ranged upwards, however, to 3.3 in Sunderland, 3.5 in Rhondda, and to 5.3 both in Bootle and in Hanley. The deaths attributed to diarrhoes in the 76 towns, which

had in the five preceding weeks declined from 676 to 348, further fell last week to 263, but caused annual deathrates ranging upwards to 2.2 in Handsworth, 2.3 in Hull, 3.1 in Rhondda, and 4.5 in Bootle. The fatal cases of whooping-cough, which had been 73, 59, and 51 in the three previous weeks, rose again to 55 last week; the highest annual rates from this disease during the week being 1.1 in Swansea and 1.2 in Wigan. The 43 deaths from diph-theris showed a further increase on the numbers returned in recent weeks, and included 14 in London and its suburban districts, three in Hanley, three in Birmingham and King's Norton, and three in Manchester and Salford. The 32 fatal cases of scarlet fever also showed an increase; 13 occurred in London and its suburban districts, three in Bir-mingham, four in Manchester and Salford, and two in Stockport. The 21 deaths referred to "fever" exceeded the number in the previous week by four, and included three in Manchester and Salford, three in Sheffield, and two in Sunderland. The 17 fatal cases of measles showed a further considerable decline, and were fewer than in any previous week of this year. The number of scarlet fever patients under treatment in the Metropolitan Asylums and the London Fever Hospitals, which had steadily increased in the five preceding weeks from 2347 to 2686, had further risen to 2737 on Saturday last; 373 new cases of this disease were admitted to these hospitals during last week, against numbers increasing steadily from 245 to 438 in the six preceding weeks. Of the 1079 deaths registered in London last week, 132 were referred to pneumonia and other diseases of the respiratory system, against 130 and 149 in the two preceding weeks, and were equal to the corrected average number in the corresponding week of the five years 1904-08. The causes of 28, or 0-7 per cent., of the deaths registered in the 76 towns last week were not certified either by a registered medical practitioner or by a coroner. All the causes of death registered during last week were duly certified in Leeds, Bristol, West Ham, Bradford, Newcastle-on-Tyne, Hull, and in 55 other smaller towns; the 26 uncertified causes of death in the 76 towns last week included seven in Birmingham, five in Liverpool, and two in St. Helens.

HEALTH OF SCOTCH TOWNS.

In eight of the principal Scotch towns 814 births and 470 deaths were registered during the week ending Oct. 2nd. The annual rate of mortality in these towns, which had been equal to 12 · 1 and 13 · 8 per 1000 in the two preceding weeks, declined again to 13.1 in the week under notice. During the 13 weeks of the past quarter the annual death-rate in these Scotch towns averaged 12.6 per 1000, and exceeded by 0.7 the mean rate during the same period in the 76 large English towns. The annual death-rates last week in these Scotch towns ranged from 8.5 and 9.4 per 1000 in Perth and Greenock to 17.6 in Paisley and 17.9 in Dundee. The 470 deaths from all causes in the eight towns showed a decline of 24 from the number returned in the previous week, and included 48 which were referred to the principal epidemic diseases, against 47 and 52 in the two preceding weeks. These 48 deaths were equal to an annual rate of 1.3 per 1000, which was slightly below the mean rate from the same diseases last week in the 76 English towns. The 498 deaths from these diseases in the Scotch towns last week included 22 from diarrhosa, eight from diphtheria, seven from "fever," six from scarlet fever, and five from whoopingcough, but not one either from measles or small-pox. deaths attributed to diarrhosa in the eight towns, which had steadily declined in the five preceding weeks from 47 to 20, rose again to 22 last week, of which nine occurred in Glasgow, eight in Edinburgh, and three in Leith. The eight deaths from diphtheria corresponded with the number in the previous week, and included four in Glasgow and two in Edinburgh. Of the seven deaths referred to "fever," of which five occurred in Glasgow, and one each in Aberdeen and Paisley, five were certified as cerebro-spinal meningitis, and one each as enteric and typhus. The six fatal cases of scarlet fever included two both in Glasgow and in Edinburgh; and three of the five deaths from whooping-

exceeded by five the number in the corresponding weeks of last year. The deaths returned in the eight towns last week included 22 which were referred to different forms of violence, of which eight occurred in Glasgow, five in Edinburgh, three in Dundee, and two in Greenock. The causes of 24, or 5-1 per cent., of the deaths in the eight towns last week were not stated or not certified; in the 76 English towns the proportion of uncertified causes of death last week did not exceed 0.7 per cent.

HEALTH OF DUBLIN.

The annual rate of mortality in Dublin, which had been equal to 16.8, 17.3, and 19.5 per 1000 in the three preceding weeks, declined again to 17.5 in the week ending Oct. 2nd. During the 13 weeks of the past quarter the death-rate in the city averaged 17 2 per 1000, whereas the mean rate during the same period did not exceed 11 4 in London and 12.3 in Edinburgh. The 134 deaths of Dublin residents during last week showed a decline of 15 from the number returned in the previous week, and included nine which were referred to the principal epidemic diseases, against numbers declining steadily from 37 to 10 in the five preceding weeks. These nine deaths were equal to an annual rate of 1.2 per 1000, the rate from the same diseases last week being 1.3 in London and 2.2 in Edinburgh. Of these nine deaths from the principal epidemic diseases in Dublin last week, five resulted from diarrhoea, two from "fever," and two from whooping-cough, but not one from measles, scarlet fever, diphtheria, or small-pox. The fatal cases of diarrhoes in Dublin have steadily declined in the last six weeks from 30 to five. Of the 134 deaths at all ages in the city last week 20 were of infants under one year of age and 44 of persons aged upwards of 60 years; the deaths of infants showed a marked decline from the recent weekly numbers. Four inquest cases and four deaths from violence were registered during the week, and 56, or 41.8 per cent., of the deaths occurred in public institutions. The causes of three, or 2.7 per cent., of the deaths in Dublin last week were not certified either by a registered medical practitioner or by a coroner; in London the cames of all but one of the 1079 deaths were duly certified, while in Edinburgh the proportion of uncertified causes was equal to 9.2 per cent.

THE SERVICES.

ROYAL NAVY MEDICAL SERVICE.

In accordance with the provisions of Her late Majesty's Order in Council of April 1st, 1881, Fleet-Surgeon Charles Geekie Matthew has been placed on the Retired List at his own request (dated Sept. 30th, 1909).

The following appointments are notified:—Surgeon: W. Bradbury to the Vulcan, additional, lent temporarily. Civil Practitioner: T. Derrick to be Surgeon and Agent at Dysart.

ARMY MEDICAL SERVICE.

Lientenant-Colonel Edward Butt, from the Royal Army Medical Corps, to be Colonel, vice J. G. Harwood, retired (dated Sept. 15th, 1909).

ROYAL ARMY MEDICAL CORPS.

Major G. Dansey-Browning has been appointed to the Aldershot Command as Assistant Sanitary Officer. Lieutenant C. Cassidy has been selected for employment with the Egyptian Army. Major H. O. B. Browne-Mason and Captain H. Simson have been appointed to India. Captain Francis Spring Walker has been appointed medical officer in command of effective troops at Crownhill (Plymouth). Captain Arthur Henry MacNeill Mitchell has been appointed medical officer in command of effective troops at Plymouth.

INDIAN MEDICAL SERVICE.

and Paisley, five were certified as cerebro-spinal meningitis, and one each as enteric and typhus. The six fatal cases of scarlet fever included two both in Glasgow and in Edinburgh; and three of the five deaths from whooping-cough occurred in Edinburgh. The deaths referred to diseases of the respiratory system in the eight Scotch towns, which had been 25, 41, and 59 in the three preceding weeks, further rose to 66 in the week under notice, and

Captain (dated Feb. 1st, 1909): William Anderson Mearns. To be Lieutenants (dated Jan. 30th, 1909): Henry Charles Gustavus Semon, Andrew Monro Jukes, Gwilym Gregory James, William David Keyworth, Berkeley Gale, John Howard Horne, Harold Holmes King, Richard Edward Flowerdew, Mozaffer Din Ahmed Kureishi, John Glendinning Bryden Shand, and Alfred John Lee.

The King has also approved of the transfer to the temporary Half-pay List of the following officers: Captain Richard Francis Chetwynd Talbot (dated July 24th, 1909).

His Majesty has also approved of the following retirements:—Lieutenant-Colonel Terence Humphreys Sweeny (dated March 1st, 1909), Lieutenant-Colonel Francis Frederick Perry, C.I.E. (dated June 14th, 1909), Lieutenant-Colonel Stephen Little (dated June 22nd, 1909), Lieutenant-Colonel Richard John Baker (dated August 12th, 1909).

TERRITORIAL FORCE.

King's Colonials: Surgeon-Lieutenant William S. Henderson to be Surgeon-Captain (dated April 1st, 1908).

Royal Army Medical Corps.

1st Welsh Field Ambulance: Lieutenant Thomas Smyth resigns his commission (dated Sept. 3rd, 1909).

3rd Wessex Field Ambulance: Captain Herbert J. Godwin resigns his commission (dated August 25th, 1909).

1st Western General Hospital: Llewellyn Arthur Morgan to be Captain, whose services will be available on mobilisation (dated Sept. 22nd, 1909).

Attached to Units other than Medical Units.—Lieutenant Alan Ayre-Smith to be Captain (dated May 22nd, 1909). Captain Edmund P. I. Coke resigns his commission (dated Sept. 13th, 1909).

For Attachment to Units other than Medical Units.—John Orton Hollick to be Lieutenant (dated August 12th, 1909).

DEATHS IN THE SERVICES.

Brigade-Surgeon William Pearson Ward (late Royal Artillery), recently at Hove, in his 86th year. He joined the medical staff of the army in 1847 as assistant surgeon, became surgeon in 1855, surgeon-major in 1867, and retired in 1880. He served through the Crimean campaign of 1854-55, and was present at the affair of McKenzie's Farm, the battles of Alma, Balaclava, Inkermann, and the siege of Sebastopol, including the assault on the Redan. He was also present at the bombardment and surrender of Kinburn (medal with four clasps, a Knight of the Legion of Honour, and Turkish medal).

TUBERCULOSIS IN THE NAVY.

Replying to Mr. Summerbell in the House of Commens on Oct. 5th. Mr. McKenna said that the number of officers and men finally invalided from the service (including Marines) for tuberculosis for the years 1899 to 1908 was 2673, made up as follows: 1899, 207; 1900, 165; 1901, 232; 1902, 288; 1903, 334; 1904, 353; 1905, 331; 1906, 214; 1907, 266; 1908, 283. No special provision was made for their treatment on their discharge from a home or hospital. In reply to a further question, the First Lord of the Admiralty said that all men before being accepted for service were medically When they were discharged suffering from tuberexamined. culosis no notification was sent to the medical officer of any particular town.

A DIRECTORY OF THE PUBLIC HEALTH SERVICE. -Acting on suggestions from many quarters, the Editor of the Medical Officer will publish early in the new year a directory of the whole Public Health Service in England, Scotland, and Wales. The directory will be on entirely new lines, and will include full particulars of the whole staff of sanitary authorities and school inspection officials. If any medical officer has not received a form for filling up he is requested to communicate with the Editor at 36, White-friars-street, E.C. It is hoped that the forms will be returned at once, as otherwise the labour of compiling the directory will be greatly increased. We have received a special number of the *Medical Officer* containing the bound and indexed records of the Health Congress held in Leeds in July as they appeared daily during that Congress, of which the Medical Officer was the official journal. Copies can be obtained for 2s. post free from the above address.

Correspondence.

"Audi alteram partem."

THE TREATMENT OF SYPHILIS BY INTRA-MUSCULAR INJECTIONS OF INSOLUBLE PREPARATIONS OF MERCURY.

To the Editor of THE LANCET.

SIR,—With reference to Major H. C. French's paper in THE LANCET of Sept. 25th, pp. 920 st seq., entitled "The Treatment of Syphilis by Intramuscular Injection of Insoluble Salts of Mercury as Contrasted with the Inunction Method," and which purports to be a critical rejoinder to a paper of mine read last June before the American Medical Association at Atlantic City, I would point out, in the first place, that the use of the term insoluble satts of mercury is not applicable to grey oil, the mercury in that preparation being in a metallic state.

I will now reply to Major French's criticisms and contradictions. As to my statement that many British dermatologists gave evidence before the Army Commission of Inquiry adverse to the use of mercurial cream, although apparently they had no actual experience of the method, it

is correct, and I maintain it.

Major French says that I omitted the deaths on record in the British army in the report of the above Commission of I did omit them, although they bear out my contention and would have lent further support to my argument, and for a very good reason. I did not consider it necessary to refer to our army in the matter, and I limited myself to oft-quoted fatal cases that had occurred abroad. As Major French has thought fit to publish the British army cases in the columns of THE LANCET, cases which, I should like to add, date from 1900-01, when the method was not perfected and men were feeling their way, I am bound to examine them. With regard to those cases reported by Surgeon-General Fawcett, R.A.M.C., it would certainly be interesting to have details as to the condition of the patients, previous illnesses, and also the state of the mouth and teeth, urine, &c., before and during the treatment by means of injections of mercurial cream. I take this opportunity of saying that I have never myself used the mercurial cream as employed in the British army, but French preparations of huile grise only.

Major French says he "never gives more than six weekly injections of 10 minims each of the standardised mercurial cream (Lambkin's formula)." He adds: "This contains one grain of metallic mercury in each dose. I allow an interval of from two to three months, then another course as above,

and so on for two years."

Before taking Surgeon-General Fawcett's four first cases seriatim I would point out in limine that doses of two grains of metallic mercury were injected each time, double the dose mentioned by Major French. This is definitely stated for Cases 1, 2, and 4 in the details published in THE LANCET by Major French himself, which I have before me. As to Case 3, the dose is not definitely stated, but I think I may assume, going by the dates, that the same preparation was

used for this patient also.

Now as to the cases. Case 1: The patient had, it is stated, 36 grains in a period of 30 weeks—viz., 18 injections of two grains of mercury each. In Case 2 the patient received 32 grains of metallic mercury in injection (16 injections in all of two grains Hg each) from Dec. 18th, 1900, to May 1st, 1901—that is to say, 18 weeks. As to Case 3, the patient had 19 injections of standardised grey oil, but the doses given are not mentioned. I think I am justified, however, in assuming, and Major French will correct me if I am mistaken, that the amount of mercury was $17 \times 2 = 34$ grains over a period of 32 weeks (June 6th, 1900, to Feb. 7th, 1901), followed on March 13th and 27th by two more, making a total of 38 grains. This case was not fatal, but the patient was very ill. Case 4: This patient received nine injections of mx. (gr. 2 of Hg) = 18 grains from January 19th to

¹ The Intramuscular Treatment of Syphilis, with Special Reference the Insoluble Preparations of Mercury: a Critical Review, HE LANCET, July 24th, 1909, pp. 212 et seq. to the Insoluble Preparations of Mercu THE LANCET, July 24th, 1909, pp. 212 et seq.

April 10th, 1901, that is, say, 12 weeks. This patient recovered.

Summarising these four cases, two of which terminated fatally, the patients received weekly quantities of mercury which work out as follows:—Case 1: 36 grains over a period of 30 weeks = 1_1 grains a week for 30 weeks. Case 2: 32 grains over a period of 18 weeks = 1_2 grains a week for 18 weeks. Case 3: 34 grains over a period of 32 weeks = 1_1 grains a week for 32 weeks. Case 4: 18 grains over a period of, say, 12 weeks = 1_2 grains a week for 12 weeks.

Let us compare these figures with those based on Major French's six weekly injections of one grain each followed by from two to three months rest. Here we have, allowing two months rest, six grains of Hg over a period of 14 weeks = \frac{3}{2} grain a week; or allowing three months rest, six grains of Hg over a period of 18 weeks = \frac{1}{2} grain a week. Comparing the latter with the period of 18 weeks of Case 2, during which the patient received 32 grains in all, or 1\cap{7} grains a week, nearly two grains, the discrepancy is great.

Taking two of the periods recommended by Major French, we have, with two months rest, 12 grains of Hg given over a period of 28 weeks = $\frac{5}{2}$ grain a week; and allowing three months rest we have 12 grains of Hg over a period of 36 weeks = $\frac{1}{2}$ grain a week. Compare this with Case 1, in which the patient received 36 grains in 30 weeks, or 1_{1}^{1} grains a week; or with Case 3, in which 34 grains were injected over a period of 32 weeks, or 1_{1}^{1} grains a week; or, again, with Case 4, in which 18 grains were given in 12 weeks, or $1_{\frac{1}{2}}$ grains a week. If it be objected that the periods should be reckoned from the first injection to the twelfth, and that is making a concession of time to Major French, we have with two months rest 12 grains of Hg distributed over a period of 20 weeks = $\frac{3}{2}$ grain a week; or, with three months interval, 12 grains over a period of 24 weeks = $\frac{1}{2}$ grain a week.

On Major French's own showing the amount injected should be somewhere about half a grain a week. It is a pity that Major French in his obvious desire to crush me with his critical rejoinder did not examine these four cases a little more critically before quoting them. I repeat I did not include them in my American paper, although these cases would have supported my contention that in fatal cases and in bad cases of stomatitis the doses of mercury had been too large. Indeed, when I was preparing my paper I decided to leave out all references to cases occurring in British army practice, and I limited myself to the examination of cases recorded in civil practice, so that Major French's contradiction of my statement that intramuscular injections of insoluble mercurial preparations are not employed to any extent in England and the United States does not amount to anything. Incidentally in my paper I did refer to the fact that the method was used in the British army, thanks to the efforts of Colonel Lambkin, whose pioneer work deserves every recognition. Perhaps Major French overlooked this when he read my paper, but I think that before contradicting me so categorically he might have done me the honour of making sure of his ground.

I do not mind meeting Major French half way by

I do not mind meeting Major French half way by examining the four cases reported by Surgeon-General Fawcett and which occurred in Egypt, but I refuse to follow him to India and to go east of Suez. Syphilis among soldiers in India needs to be taken very much on its merits. East is East and West is West,

"And the wildest dreams of Kew are the facts of Khatmandhu, And the crimes of Clapham chaste in Martaban."

Major French misquotes me when he says that I state: "I have only employed the intramuscular injections in my private practice. No ill-effects ensue after 10-12 consecutive weekly injections of doses varying from 1-10 centigrammes." What I really did say is this: "As far as my own work goes, I may say I have only employed the intramuscular injections of insoluble preparations in my private practice. I have never seen any complications arise. My results have been very satisfactory and I consider the method a most valuable one, especially when any serious syphilitic complication threatens. My experience of the carly abortive intense (italics are in my paper) treatment has been from the nature of private practice very limited, and I have not felt justified in applying it to its full extent. But where full control of the patient could be obtained I have found no ill-effects ensue after 10 or 12 consecutive weekly injections of doses varying from 7 to 10 centigrammes."

I would insist here that my reference to the use of 10 to 12 injections relates to the so-called early intense abortive treatment of syphilis, and not to ordinary treatment. Major French's mangled quotation of my printed words is a missepresentation of my views and practice. To take two sentences totally unrelated to each other and quote them in direct consecutive order—that is, without any indication that there were other sentences between them—is an unwarrantable procedure. The matter is made worse by the remarks of Major French which immediately follow his misquotation of what I said and wrote. I insist on this, as such a way of putting it must necessarily create prejudice.

As to other points, I may tell Major French that in his references to severe mercurial dermatitis he is sending coals to Newcastle as far as I am concerned.

His remarks as to Professor Fournier's attitude in the matter of insoluble preparations are not up to date. I know Professor Fournier and his son, Dr. Edmond Fournier, personally. They both employ huile grise in intramuscular injection. Indeed, it is not so long ago that a patient was directed to me with a request from Professor Fournier himself that I should continue injections of huile grise in the case. I have habitually used Dr. Edmond Fournier's syringe specially devised for huile grise, to which I alluded in my paper.

With regard to the two fatal cases following inunction treatment, one of which I took from the practice of Dr. Mayer of Aix-la-Chapelle,² the fact remains that the inunctions led to a fatal issue. These are not the only two cases that might be brought forward against the inunction treatment, but I was careful to add in my paper that "that would surely be no reason for damning a method that is valuable."

In my American paper I dealt fairly and squarely with the whole matter, as far as the limits of time would allow me. I stated distinctly that in the treatment of syphilis I was eclectic as to the method to be employed; all methods had their place. Moreover, I insisted on the importance of not treating cases by intramuscular injections of insoluble preparations in a routine way, adding that in certain circumstances which I enumerated, insoluble preparations were absolutely contra-indicated. I did not advocate their use for all and sundry, but put in a plea for a better recognition of a valuable addition to our armamentarium in fighting syphilis. I looked at all sides of the question and did my best. I may say that at Atlantic City, although many among my audience were not favourably inclined to insoluble preparations of mercury, they quite appreciated the fact that I had dealt with the method frankly and fairly, and that I had pointed out its dangers as well as its advantages.

I am, Sir, yours faithfully, Harley-street, W., Sept. 27th, 1909. GEORGE PERNET, M.D.

IS SNOW-WATER UNWHOLESOME?

To the Editor of THE LANCET.

SIR,—If I may add a few words to the discussion upon the influence of snow-water that has been taking place in your columns recently I should like to draw attention to some interesting though almost forgotten observations made amongst the Cree Indians in North-West Canada in the year 1819-20, by John Richardson, M.D., F.R.S., F.L.S., who accompanied Captain John Franklin, R.N., F.R.S., upon the first and second of his voyages to the shores of the Polar seas in search of the North-West passage.

Dr. Richardson's observations in his own words are as follows: "Bronchocele, or goitre, is a common disorder at Edmonton. I examined several of the individuals afflicted with it, and endeavoured to obtain every information on the subject from the most authentic sources. The following facts may be depended upon. The disorder attacks those only who drink the water of the river. It is indeed in its worst state confined almost entirely to the halfbred women and children, who reside constantly at the fort, and make use of river water, drawn in the winter through a hole cut in the ice. The men, being often from home on journeys through the plain, when their drink is melted snow, are less affected; and, if any of them exhibit during the winter some incipient symptoms of the complaint the annual summer voyage to the sea-coast generally effects a cure. The natives who confine themselves to snow water in the

1102 Tes Larons,]

winter, and drink of the small rivulets which flow through the plains in the summer, are exempt from the attacks of this disease. These facts are curious, inasmuch as they militate against the generally received opinion that the disease is caused by drinking snow-water—an opinion which seems to have originated from bronchocele being endemial to subalpine districts. The Saskatchawan, at Edmonton, is clear in the winter, and also in the summer, except during the May and July floods. The distance from the Rocky Mountains (which I suppose to be of primitive formation) is upwards of one hundred and thirty miles. The neighbouring plains are alluvial, the soil is calcareous and contains numerous travelled fragments of limestone. At a considerable distance below Edmonton, the river, continuing its course through the plains, becomes turbid, and acquires a white colour. In this state it is drunk by the inmates of Carlton House, where the disease is known only by name. It is said that the inhabitants of Rocky Mountain House, sixty miles nearer the source of the river, are more severely affected than those at Edmonton. The same disease occurs near the source of the Elk and Peace Rivers; but, in those parts of the country which are distant from the Rocky Mountain Chain, it is unknown, although melted snow forms the only drink of the natives for nine months of the year. A residence of a single year at Edmonton is sufficient to render a family bronchocelous. Many of the goitres acquire great sise. Burnt sponge has been tried and found to remove the disease, but an exposure to the same cause immediately reproduces it. A great proportion of the children of women who have goitres are born idiots, with large heads, and the other distinguishing marks of cretins. I could not learn whether it was necessary that both parents should have goitres, to produce cretin children; indeed, the want of chastity in the half-bred women would be a bar to the deduction of any inference on this head."

I am, Sir, yours faithfully

Wimpole-street, W., Oct. 5th, 1909.

HERBERT FRENCH.

DOMICILIARY MEDICAL TREATMENT UNDER THE POOR-LAW.

To the Editor of THE LANCET.

Sire,—With your permission I should like to say a few words about the "two most cogent reasons" that Dr. H. Beckett-Overy refers to in his letter published in your issue of Oct. 2nd, p. 1026, which he objects to being defined as "mere negations." The first reason I specifically dealt with, and pointed out the impossibility of recovering charges by any legal process from "poor persons," where the first requisite under any enactment would be to prove ability to pay. I instanced the failure in the past to recover anything beyond the most trivial proportion of the relief granted "on loan" under the present system, the principle of which is indistinguishable from that recommended by both the Majority and Minority Commissioners. The restatement of these recom-mendations without any reference to my criticism Dr. Beckett-Overy does not consider a "mere negation." In his last letter he states that £300,000 have been recovered in various ways by all the authorities having any connexion with the Poor-law. That this is an attempt to meet my criticism I am quite ready to admit, but I demur to its cogency. For aught I know, the £300,000 recovered may be as trifling a proportion of the amount expended as the "relief on loan" recoveries. The inclusion of lunacy institutions nullifies any value it might have as a comparison, as it is notorious that the great bulk of the middle classes of the country make use of these instead of private institutions, with the full knowledge that they must pay for their relatives. From many of these no doubt the cost could be readily recovered. With regard to the second reason-viz., the effect that inability to choose their doctor would have in preventing abuse of gratuitous medical attendance—nothing was said in Dr. Beckett-Overy's first letter, unless it is to be inferred from the general approval of the views of the Minority Commissioners. I admit I called it a mere negation, and do not see why I should alter my opinion. The suggestion now made that this would be a sufficient check is, in my opinion, a very weak argument. No doubt, among the large class of poor persons to whom I refer, most would prefer to choose their doctor, but I have no hesitation

in saying from the experience of a lifetime among that class that the choice would be largely swayed by the cost to them-Where State-guaranteed medical attendance could be had for nothing it would show very unusual belief in a particular doctor for the patient to prefer the latter if he had to pay him. It is a fact only too cognisant to practitioners among the poor that a difference of sixpence in the fee will detach a patient from a doctor who has attended him for years and send him to an unknown new-comer.

I am, Sir, yours faithfully. London, Oct. 2nd. 1969.

MAJOR GREENWOOD.

DISPENSERS IN PUBLIC INSTITUTIONS FOR THE SICK.

To the Editor of THE LANCET.

SIR.—I am instructed to forward you a copy of a letter dealing with the question of dispensing in public institutions which has been drawn up by the National Union of Assistant Pharmacists and which is to be sent to those concerned as occasion arises. - I am, Sir, yours faithfully,

EDW. S. FRANCIS, M.P.S., 9. Honorary General Secretary. Birmingham, Sept. 29th, 1909.

[COPY.]

[COPT.]

The National Union of Assistant Pharmacists has considered the question of dispensing in public institutions and has decided that it in the public interest that the attention of public bodies and others having the appointing of a dispenser should be drawn to the following facts and for which we respectfully ask your consideration:—

(1) The Pharmacy Act restricts the open sale of poisons to duly qualified "chemists and druggists" who have been trained and examined by the Pharmaceutical Society, so that they are fully informed as to the nature and properties of poisons. We submit that it is a necessity for the public safety that poisons which are dispensed in large quantities in public institutions should be under the control of a fully qualified individual, and we therefore ask you to appoint a registered "chemist and druggist" (i.e., a pharmacist) as dispenser.

(2) The remuneration officred for the services of a dispenser is frequently such as to admit only of securing persons holding certificates other than the diploma of the Pharmaceutical Society (the recognised standard of efficiency), and as the training for the diploma is long and expensive, we consider £130 per annum to be the minimum salary, irrespective of sex, for the professional and responsible services of a dispenser.

We seek your support in securing to us these rightful conditions in

dispenser.

We ask your support in securing to us these rightful conditions in recognition of the fact that it is necessary for us to undergo special training in the interests of the safety and service of the community.

Signed on behalf of the National Union of Assistant Pharmacists.

THE BENHAM TOP.

To the Editor of THE LANCET.

Sir,—In Dr. F. W. Edridge Green's valuable paper on the Theory of Vision, published in THE LANCET of Oct. 2nd, brief reference is made to the Benham top, and an explanation is offered to the effect that the lines appear red because this is the contrast colour to the green which is seen as the after-image of the black half of the disc. Assuming that black does give an after-image of green to normal sight in a bright light, Dr. Edridge-Green seems to overlook the fact that the lines being themselves black should have an after-image of green. In a paper by Mr. F. Peake Sexton published in the Illuminating Engineer last May what has seemed to me a complete explanation of the colour effects in the Benham top has been offered. His theory is based on the fact that the duration of the impression of light on the retina varies for different wave lengths, and he shows how this circumstance completely accounts for all the colour effects of the top and their reversal on reversing the direction of rotation. It is a question of the rate both of growth and decay of colour sensation.

Colchester, Oct. 1st, 1003.

I am, Sir, yours faithfully, CHARLES E. BENHAM.

CHRISTIAN SCIENCE IN RELATION TO THE WORKMEN'S COMPENSATION ACT.

To the Editor of THE LANCET.

SIR.—What is the doctor's duty in the following case? very intelligent artisan, whom I had been treating some two years ago for syphilis, came to me recently complaining of giddiness, reeling, and other cerebral symptoms which I concluded were caused by a syphilitic tumour. Having plainly expressed my opinion, I told him that it was probable he would be cured if he continued treatment long enough. "I came to you," quoth he, "for diagnosis, not for treatment.

I have joined the Christian Scientists and cannot take any of your medicines. I believe I shall be cured by prayer treatment." In reply, I stated that as his work involved going up and down ladders constantly there would be grave danger that the tumour would result, if untreated, in his falling off the ladder, with perhaps fatal results. I hinted that although he might have made up his mind to chance his own life, still it would not be fair to have his employer mulcted for a fatal accident which was the result of his own obstinacy. Hence I suggested it was his duty to inform his employer of the fact that he had a cerebral tumour and declined treatment.

The man candidly confessed that the employer, although insured, would certainly dismiss him if he know the truth, but he refused treatment. Does any duty lie on the practitioner to inform the employer, either to save the man's life or the employer's pocket? In my opinion the duty of the doctor is only to the patient, but I should like to hear other opinions on the case.—I am, Sir, yours faithfully,
J. C. McWalter, M.D. Brux., F.F.P. Glasg.

Dublin, Oct. 3rd, 1909.

DEATH CERTIFICATION AND CORONERS. To the Editor of THE LANCET.

SIR,—Referring to the case of the coroner and Dr. F. C. Coley, published in THE LANCET of July 24th, p. 243, I should like to give you particulars of a similar case which came under my notice in which the coroner told me to give a certificate. An electrician to a pit was attending to my electric bells one evening, when he asked me to examine his chest on account of a pain from which he was suffering. I diagnosed heart disease and told him that he should rest for three months. I had never seen the man before and did not see him alive again. One morning some months afterwards I was called up to the pit where he worked to see a man who had died suddenly. The deceased turned out to be the electrician. I happened to mention the fact that I had advised him to rest, and so on, which information was retailed to the coroner's officer when he reached the pit, and in due course came to the ears of the coroner, who telephoned me asking me to give the certificate, though a period of some months had elapsed since I had seen him the one and only time.

Only recently I gave a certificate of death "due to ptomaine poisoning," at the same time out of courtesy telephoning the coroner that I had done so, and that the primary cause was probably ice-cream. I was much surprised to hear from him that I ought not to have given a certificate, though the patient had been visited three times in 24 hours by my colleague and myself, thus establishing attendance during last illness, and on asking if I should do a post-mortem examination was told that if I were able to give a certificate I could surely satisfy the jury as to the cause of death without a post-mortem. I hold that there should not have been any inquest, or, if one was deemed necessary, a post-mortem examination should also have been made. I am, Sir, yours faithfully,

THE BOOTS OF THE TERRITORIAL ARMY.

To the Editor of THE LANCET.

SIR,-Your correspondent, in his interesting article on the Territorial Medical Service in THE LANCET of Sept. 25th, draws attention to some of the disabilities which cause bad marching amongst the troops. Whilst endorsing all he says as to the importance of keeping the feet clean, I think the necessity for adequate covering for them requires an equal amount of consideration. As the result of a "foot inspection parade," and from cases which reported sick, I found a great number of the men suffered after the first day or two of marching during the late camp on Salisbury Plain from "blisters on the soles of the feet," abrasions, and cracks about the heels and over the dorsum of the foot, due chiefly to the unsatisfactory boots worn by most of the troops. I found these lesions frequently present even amongst those of the men who were particular in keeping the feet clean.

allowed to each man is of little use to him in obtaining a good pair. The result is that in many of the regiments a great variety of "foot-wear" is in use, and a lot of the boots fit badly and are evidently of a peer quality. Since my return from camp I have been shown by a practical bootmaker a cheap and very commonly used form of brown boot, cut down the centre from top to toe. Under a thin leather sole there is a pad consisting apparently of brown paper; this readily, on wet roads and from the heavy dew on the grass noticed at each early morning parade, gets soaked through and remains sodden. As the men have no means of drying their boots they are obliged to wear them in this condition, resulting, I feel sure, in chills and an unhealthy state of the skin of the soles of the feet, causing them easily to blister and crack. The plucky way a great many of the men continued to march with their feet in the painful condition I frequently noticed is another proof of the general keenness mentioned in most of the daily papers. I am told that it is possible to supply an excellent brown boot made of good leather, and treated by a new process, whereby it is rendered absolutely and permanently waterproof; my bootmaker informs me this process is known as the "Forbec." Boots made of this leather can be obtained for 10s. per pair. The objection, I suppose, to issuing boots to the men is that they might use them for other purposes than service use, but surely this could be got over, as I believe it is in the regular army, by making a man either produce the boots issued (in the case of a Territorial before he goes to camp) or getting himself a similar pair and deducting the cost from his pay if necessary.

I am, Sir, yours faithfully,
LIEUTENANT, R.A.M.C.T.

Oct. 2nd, 1909.

BRISTOL AND THE WESTERN COUNTIES.

(FROM OUR OWN CORRESPONDENTS.)

The University: Reception of Students.

THE University session opened on Sept. 30th with Sir Isambard Owen's address, and on the evening of Oct. 2nd a reception was held at the University for students and staff. Mr. Lewis Fry, on whose behalf the invitations were issued, was unwell and could not be present; but the guests were received by Lady Owen, Professor and Mrs. Lloyd Morgan, and Professor and Mrs. Michell Clarke. Music was provided by the University Musical Society, under the direction of Mr. Cedric Bucknall, the University lecturer in music. All round the hall in which the reception was held were ranged tables at which various student societies, over 20 in number, were represented. These will, it is hoped, be united into a guild of undergraduates, which was provided for under the charter. In the centre of the room was a stand exhibiting various objects of interest brought home by Lieutenant Shackleton's Antarctic Expedition. These were kindly provided and supervised by Mr. R. E. Priestley, who was geologist to the expedition, and whose brother is lecturer on botany to the University. There was a very large number of students present, and the staff was well represented also.

Hostel for Bristel University.

Clifton Hill House, formerly the residence of Dr. Symonds, has been purchased as a hostel for Bristol University. Two ladies have subscribed £2000 towards the cost of the undertaking.

The Glowcestershire Royal Infirmary.

At the quarterly general meeting of the governors of the Gloucestershire Royal Infirmary held on Sept. 30th the chairman (Colonel Curtis Hayward) stated that the expenditure of the institution last year exceeded the income by £1000. He added that the committee had decided, unless it had increased financial support, that it would reduce expenses by closing a ward and reducing the number of nurses. Colonel Hayward added that this would be a calamity for the city and county, but he was afraid the present generation did not quite appreciate its duty towards the infirmary, the work and cost of which were ever increasing.

The Declining Birth-rate.

It appears that no boots are issued to the Territorial A member of the Bristol education and health committees coldier on enlistment, and the 2s. 6d. boot money has drawn attention to the declining birth-rate at Bristol. A member of the Bristol education and health committees The matter was alluded to at a recent meeting of the health committee, when it was stated that in 1884 the birth-rate was 32.6, a year ago it was 24.2, and now it is as low as 23.

Medical Inspection of School Children.

At a meeting of the Tavistock (Devon) school attendance sub-committee held recently it was reported that some parents had objected to their children being examined in an elementary school by the county medical officer of health. It was stated that the law allowed the parents to act in this manner, and the sub-committee, after some discussion, decided to recommend the county authority to take steps, if possible, to get the law amended so as to prevent parents being able to withdraw their children from medical inspection.

The Devon County Council and the Prevention of Consumption.

The Devon County Council at its last meeting decided to purchase and circulate pamphlets of the National Association for the Prevention of Consumption. The council further determined that the education committee be requested to consider the question of providing instruction as to the means which should be adopted to secure protection against tuberculosis, and the council also suggests that the scheme of instruction should include the giving of demonstrations and the holding of exhibitions.

Bristol Royal Infirmary.

Mr. Francis Tagart has promised £1000 towards the extinction of the adverse balance remaining over from the infirmary accounts of the last financial year.

Oct. 4th.

MANCHESTER.

(FROM OUR OWN CORRESPONDENT.)

'The Work of the Corporation Sanitary Committee.

THE general work of the sanitary committee has been very considerable. It has during the year dealt with, in one way or another, 14,272 houses, warehouses, and other buildings, 1582 lodging-houses, 3176 dairies and milkshops, 4644 infectious cases, drainage, the sanitary accommodation of beerhouses, 3257 houses under the Factory Acts, 510 bake-houses, fire-escape provision in factories and workshops, the hours of work in shops, the provision of seats for assistants, and many other things. During the year 2335 insanitary dwellings were certified to the committee. Of these 2164 were ordered to be closed, while the decision on 171 was adjourned, but as the owners of 1695 agreed to make the required alterations 469 summonses only were actually served. The corporation has a municipal lodginghouse, which has been well attended during the year, the number accommodated averaging over 343 per night. The number accommodated averaging over 343 per night. The cubicles number 353, a small margin, and it has been decided to extend the accommodation by the addition of 123 more cubicles. As regards the adulteration of food, it is not satisfactory to find a slight increase from 3.42 per cent. last year to 3.74 this year. This is accounted for chiefly by the increased number of samples of adulterated coffee and spirits. Presumably the increased tax on spirits has stimulated fraudulent ingenuity. As regards butter adulteration, it is so profitable to the dealer that it will be difficult to prevent it till the justices see fit to deal more severely with the cases brought before them. It is a sordid, mean thing to adulterate food, and those who suffer from it are the poorer classes who ought to obtain more protection from it than the law seem willing to give.

Black Smoke.

One of the difficult tasks the sanitary committee of the city council endeavours to accomplish is the diminution of the black pall of smoke usually hanging over Manchester, and it cannot be said that so far its efforts have been crowned with success. In the year ending in April last 178 cases were reported where black smoke had poured forth from chimneys for two minutes or more in the half-hour. Of these, 131 were referred to the magistrates to be dealt with, and in the other cases the offenders were cautioned. There have been great complaints of the evilsmelling black smoke given out by railway and road locomotives, and in several instances prosecutions have been

The penalties usually imposed are too trifling to necessary. check, much less to suppress, this nuisance; or to put it more euphemistically in the words of the report, the penalties "are not such as to assist the committee in the suppression of smoke nuisances." These small penalties will not, perhaps, seem so remarkable when it is remembered that most of the magistrates have been accustomed to the sight of black smoke issuing from tall chimneys since they were first able to open their eyes and to look upon this filthy emanation as an ideal part of the landscape. appeals to their commercial instinct, for many of them are interested in mills and their chimneys, and think, moreover, that black smoke is a sign of prosperity, not having been educated up to the fact that this enormous waste of fuel is unnecessary and avoidable. Manchester also suffers from the sins of her neighbours, for she is almost surrounded by a ring of tall chimneys beyond her jurisdiction, sending forth black smoke as if their existence depended on their efficiency in that variety of manufacture. Salford has for years been among these creators of a most hurtful nuisance. The tall mill chimneys are well backed up by the lower ones of various works, hotels, &c., all over the city. Of course, the black smoke and smuts pervading the town cause serious loss to those who deal in or manufacture light delicate fabrics, to say nothing of the depressing effects of constantly dwelling in such an atmosphere, or of its pernicious influence on those who have sensitive throats or chests.

Ladies as Workhouse Medical Officers.

At the meeting of the Prestwich guardians on Sept. 30th a discussion arose as to the suitability of a lady being appointed to the position of assistant workhouse medical officer. This was in consequence of five out of the six answers to the board's advertisement for applications being from ladies. It was eventually decided, however, that the board should advertise again, and that it should be made clear that the appointment could only be held by a man.

SCOTLAND.

(FROM OUR OWN CORRESPONDENTS.)

Appointments at the Western Infirmary, Glasgow.

AT a meeting of the directors of the Western Infirmary, Glasgow, held last week the following appointments were made:—Dr. J. Wyllie Nicol, physician to the wards for diseases of the skin; Dr. J. Goodwin Tomkinson, dispensary physician for diseases of the skin; Mr. A. H. Edwards, dispensary surgeon; and Dr. Roy Young, extra-dispensary surgeon.

An Epidemiological Study of Measles in Glasgow.

In his report on the severe measles epidemic which occurred last year in Glasgow, Dr. A. K. Chalmers, the medical officer of health of the city, affords food for thought to medical men and also to those interested in school board affairs. Seldom if ever before has there been opportunity for watching the rise and fall of a serious epidemic of measles in a large city owing principally to the fact that the disease is not notifiable. For some years past, however, there has been an increasing interchange of information with the school boards, and by this means in the recent epidemic the medical officer of health was informed of the names and addresses of scholars who were absent owing to the occurrence of infectious disease in themselves or other members of the family. Following upon the receipt of this, house-to-house visits were made and many other cases were thus discovered. The desire on the part of parents for disinfection also brought many cases to the notice of the sanitary department, and thus the whole volume of the disease present may be regarded to have been fairly represented in the cases dealt with, and particularly in that portion which occurred at school ages. In past experience the outbreak usually became considerably abated after the New Year holidays, but in last year's outbreak its prevalence in February and March equalled that of November and December, while in January the numbers exceeded that of any other single month. The whole duration of the epidemic was from October until April, and a notable and unusual feature was the numerous districts of

the city over which the prevalence was maintained simultaneously for a considerable time. In reviewing a chart of the death-rate from this disease for the last 50 years Dr. Chalmers points out that since the year 1871 the deathrate for individual years more frequently falls below the mean than in the years preceding the "seventies." In the period between 1855 and 1873 every second year almost shows the deaths from the disease to have been in excess of the mean. There then occurs an interval of ten years between 1873 and 1883, during which the death-rate falls below the mean for the period. But, again, from 1883 to 1897, six years only of the 14 have the death-rate below the mean, after which there follows the interval of low death-rates which was brought to a termination by the cyclical prevalence of 1907-08. According to Dr. Chalmers, if one were disposed to suggest that the general lowering of the measles death-rate in the last 30 years has been the result of active sanitary administration, there comes in the interval between 1883 and 1897 to suggest that other factors are at work, and what seems more likely is that the organism of measles undergoes fluctuation in infective power and that periods of increased prevalence correspond with the development of a high degree of infectivity. At the same time it has to be observed that even after a twelve years' interval the death-rate in 1908 is considerably below the rate which obtained in 1883, which marked the termination of the former interval of similar duration. The attack-rate during the recent outbreak was at least 17 per 100 living at ages of three to five years, compared with 5 per 100 at ages of five to 15 years. Of the 22,033 cases dealt with no fewer than 13,646, or 62 per cent., were at ages under five years. The influence of school association in the spread of measles is beyond dispute, but the contrast between the attack-rate in the first five years of life with that at ages of five to 15 years, which includes the school age, definitely raises the question, according to Dr. Chalmers, whether school closure in any form can be expected to interrupt materially the current of an epidemic, which is attacking the earlier ages at more than three times the rate prevailing among children in the period which includes those who are attending school. This gains support from a com-parison of the distribution of the disease before and after the New Year holidays. For the future it is to be hoped that medical inspection under the Education Act will help in the early recognition and exclusion of children who are displaying the first symptoms of invasion of the disease. IRELAND.

(FROM OUR OWN CORRESPONDENTS.)

The Quarterly Report of the Dublin Public Health Committee.

THE report of the public health committee of the corporation of Dublin for the second quarter of the present year (ending June 30th) has just been issued. Sir Charles Cameron reported that the necessity of making a fully detailed statement in his statutory certificate regarding the Cook-street insanitary area had been legally indicated to him. Accordingly, he had not only prepared a full statement regarding the conditions of the houses in that area (as he had done in former reports), but he included the houses (Nos. 1 to 13) on the east side of Michael's-lane, as these were all in a very bad state, and any scheme of improvement which allowed them to stand would necessarily be incomplete. A letter from the Women's National Health Association was discussed which expressed its warm approval of the plans for utilising rooms during disinfection and for the isolation of some of the worst cases of disinfection in tenement houses. An interesting section of the report is that which deals with the baths and wash-houses, to which 36,986 persons had paid for admission during the quarter. Of this number, 19,492 were visitors to the swimming-baths, of whom 777 were members of ladies' aquatic classes. The reclining baths were visited by 11,949 persons, of whom 1779 were females, including 331 Hebrew matrons, who used the special plunge bath. The private reclining bath had realised a sum of £227 12s. The public wash-house had been utilised by 5285 women during the quarter, who had paid £28 12s. 6d. for the accommodation. An invitation has been received by the

Congress of Hygiene and Demography, which is to be held at Washington next year, to appoint representatives to attend its meetings. In response to the invitation, the chairman (Alderman Thomas Kelly) and assistant executive sanitary officer (Mr. Patrick Nally) were selected, subject to the approval of the municipal council.

Glasnevin Cemetery: its Pit Burial of Paupers.

The municipal corporation of Dublin has at length decided to effect a permanent improvement in the conditions of Glasnevin Cemetery, the great central burial-ground of the Irish race. It is but too well known that two of the characteristic features of the Irish metropolis are its large number of paupers and the high rate of its mortality, two factors which are to some extent interdependent. But in this century the practical application of the time-worn maxim that "prevention is better than cure" has become an accomplished fact, for the first time in the history of medicine. And in keeping with the progress of sanitation it is gratifying to record that two of the notices of motion to be brought before the next meeting of the corporation deal with the subject of the burial of the poor. The first of these demands an expert decision (by the superintendent and district medical officers of health) of the question whether the "pit" burial at Glasnevin constitutes a public nuisance, and if so that the necessary steps be taken to stop it. The second is more comprehensive:

That the Local Government Board be requested to hold a sworn inquiry to investigate the charges made to the Corporation of Dublin that the system of burial provided for the poorer classes is neither sanitary nor decent, and that pending the result of this inquiry no further steps be taken to found a municipal cemetery.

This motion, which was partially discussed on Monday. Oct. 4th, surely deserves the best attention of the governing body of a community which has long prided itself (not without cause) on its ready sympathy with poverty and pain. It may be added that the co-existence of the colossal monuments of Glasnevin, erected in memory of individuals of more than doubtful benevolence, with its paupers' "pit" hardly claim to be worthy of either democracy or Christianity

Dublin Sanitary Association: View of the Action of the Opponents of the Iuberculosis Campaign.

At the meeting of the council of the Dublin Sanitary Association which was held last week the members discussed "the grave danger to the public health" arising from the operations at present in progress at the main drainage works, at Burgh Quay and the vicinity, and it was decided to interrogate the corporation on the subject. The debate on the prevention of tuberculosis, which had taken place at the meeting of the guardians of the South Dublin Union on the previous day, was then discussed with a keen degree of interest. The opinion was unanimously expressed that the views put forward by several of the speakers were "extraordinary, as coming from members of a sanitary authority to which the law had entrusted the safeguarding of the public health and the duty of adopting measures to control the prevalence and spread of dangerous infectious disease, to which category tuberculosis is admitted on all hands to The continuous discussion of the tuberculosis belong." problem is rapidly enlightening the general public on the importance of the questions connected with sanitation in general, as well as of those which are specially associated with the prevention of tuberculous disease.

National Maternity Hospital: Annual Charity Sermon.

The annual charity sermon in aid of the National Maternity Hospital (Holles-street) was preached on Sunday last in the Church of St. Andrew, Westland-row, and was heard by a large and representative audience, the members of which responded liberally to the appeal of the eloquent preacher. There is certainly no institution which has a higher claim on the appreciative sympathy of the public of Dublin and of Ireland. It not only receives patients in its wards, and treats them in its dispensaries, but it sends skilled nurses and medical men to the homes of the destitute poor who are prevented by unavoidable circumstances from presenting themselves at the institution. In this respect it has taken a meritorious leadership which has not up to the present been fully followed by any other of the maternity hospitals of this city. The fact that during the past year 10,432 visits of this kind were paid to the poor of the surrounding district is sufficient evidence of the extent committee from the secretaries of the Fifteenth International of its sphere of usefulness. The number of patients attended

during the past year, intern and extern included, was 1970, while 4433 gynæcological cases were treated in the dispensary. The hospital now occupies the third place in size and importance among similar institutions in the British Islands.

Health of Belfast.

During the discussion of the report presented to the meeting of the Belfast city corporation on Oct. 1st on the health of the city between August 22nd and Sept. 18th, a very curious state of affairs was disclosed in reference to the importation of a quantity of lard into Belfast from the United States in barrels with, at the ends, the words "inedible" or "non-edible." In some cases it was found that these words had been whitewashed over, and in some cases actually the officer of the public health committee watched a consignment of this stuff from the quay to the stores, and subsequently noticed men engaged in obliterating the warning words from the heads of the barrels and substituting other words. There were 140 or 150 tons of such stuff in Belfast or in course of transit at the time, and the health committee agreed that if the consignees undertook that the material should in no form be manufactured for human consumption it would remove the embargo and permit it to be used for other purposes. The firm affected agreed to this, and they also undertook never again to import or use in their works any lard or grease from the United States unless it bore the official certificate of the Government to the effect that it had been inspected and was not to be used as human food. This "inedible" grease is used in the manufacture of soap and lubricants.

Death of W. J. McDade, M.B. R. U. 1.

Great regret has been felt in Belfast at the announcement of the death in Preston of Dr. W. J. McDade, which took place in that town on Sept. 29th, in his forty-seventh year. He began to practise in Preston about six years ago, and became a member of the borough council and vice-chairman of the public health committee. Dr. McDade in his early life in Belfast was engaged in the great firm of Grattan and Co., pharmaceutical chemists, and he left them to take charge of the compounding department of the old Royal Hospital in Frederick-street, where he remained from December, 1884, to July, 1893. At the same time he pursued his medical studies at Queen's College, Belfast, and graduated M.B. of the Royal University of Ireland in 1893. A man of great energy and industry and an excellent afterdinner speaker, Dr. McDade made a great number of friends, and as an experienced practitioner he will be greatly missed in Preston. He leaves a widow. Previous to settling down in practice in Preston Dr. McDade had filled appointments in London, Lincoln, and Manchester. Oct. 5th.

PARIS.

(FROM OUR OWN CORRESPONDENT.)

Sickness in the Army.

THE average of 269 sick per 1000 of total strength of the army is higher than in previous years. This average represents the proportion of men admitted into the military hospitals, the actual number being 134,631 according to the latest statistics. These 134,631 patients were under treatment for 3,101,126 days. Algeria and Tunis supplied 25,126 hospital patients, giving a proportion of 360 sick per 1000 of the total strength, a number which is higher than in previous years. These patients were under treatment for 648,601 In the home army there were 200,686 admissions to the infirmary, giving in that respect a sickness-rate of 478 per 1000 of the total strength. This proportion This proportion is decidedly above that of previous years. These patients were under treatment for 1,954,365 days. In Algeria and Tunis the number of admissions to the infirmary was 21,876, or a proportion of 377 men per 1000 of the total strength, which is about the same as in previous years. These patients were under treatment for 258,605 days. According to the military authorities this rapid increase in sickness is due, not so much to the sanitary state of the barracks and the conditions of a soldier's life, as to the fact that men whose health was indifferent at the time of enlistment (incorporation) are placed on active duty.

Precautions against Cholera.

On account of the prevalence of cholera in Russia and Holland the President of the Council (Minister of the Interior) has laid down the following regulations with a view to prevent the importation of the disease into France. Every person who comes from a place infected with cholera and on arrival at the French frontier presents possible symptoms of this disease shall be detained at the railway station by the officer (commissaire) appointed for the purpose and shall be isolated until seen by a medical man. If the case is then considered not to be one of cholera the person shall be allowed to continue his journey, but if the case is found to be one of cholera the commissaire, acting in concert with the municipal authority, shall convey the patient to some place where, in the opinion of the medical man, isolation may be carried out under favourable conditions for the patient and for the prevention of infection. The prefect will also send a representative (délégué départmental) or a specially appointed medical man who will take all the steps that may be necessary. Similarly any person coming from a place infected with cholera and presenting suspicious symptoms shall be isolated in a compartment of the train by which he is travelling. All railway servants are bound to act in accordance with this regulation. On the train coming to a station where a commissaire resides the patient shall The carriages which have been occupied by persons suffering or supposed to be suffering from cholera shall be emptied and disinfected. Dirty linen and soiled clothing or bedding are forbidden to be brought into France by land from infected districts unless as luggage. When lodgings are taken by persons who either come direct from infected places or have left such places within the preceding eight days, the householder shall within 24 hours of their arrival notify the fact to the Maire of the commune. Every case of illness suspected to be cholera shall be immediately notified at the Mairie. Every person suffering from an illness which is either recognised or suspected to be cholera must be immediately isolated, and all measures of prevention carried out with respect both to the patient and to those who have been associated with him.

Precautions in the Granting of Medical Diplomas.

THE Vienna Professoren Collegium, which is composed of the teaching staff of the University, has informed the responsible authorities that the existing arrangements are very favourable for those who are willing to obtain a medical diploma by fraudulent means. In particular, the ease with which foreigners are allowed to obtain diplomas is full of danger, as there is no special obligation on these candidates to satisfy the degree-granting body as to the course of instruction which they claim to have had in This appeal to the authorities their own country. is directed principally against medical students from Russia, Roumania, and Servia, who can finish their studies here, obtain a diploma, and settle down here in practice, although they are not allowed by law to do so unless they become naturalised Austrian subjects. In several instances brought to the notice of the Ministry of Education lately diplomas have been obtained merely on production of documents written in a foreign language testifying that the holders had been studying during one or more terms of a medical curriculum, without saying anything about their examinations. The Ministry has accordingly instructed the medical councils to submit a scheme by which such unlawful proceedings may be stopped without inconvenience to ordinary students or to those who attend post-graduate courses of instruction.

Healthy Dwellings for the Poorer Classes.

The erection of healthy dwellings for the poorer classes has been brought into a very satisfactory condition by the exertions of a small body of medical men and philanthropists, and the jubilee of the venerable Emperor Francis Joseph last year prompted many persons to aid the scheme, so that at present there are two "colonies" of this kind in Vienna. One consists of a cluster of cottages with 400

dwellings for 2000 persons, and the other of one large building, capable of accommodating 1000 single men. The leading idea is the obtaining of light and air and comfort for as little money as possible. The minimum air-space for persons has been fixed in these dwellings at 40 cubic metres (about 1200 cubic feet), and a special point has been the absence of backyards with their universal dirt and darkness. Careful observation by the medical officer of health of the district has proved that the health of the inmates of these houses is far better than it was before they came there to live. An important point is that the health of the children has been very satisfactory. This scheme affords a proof on a large scale that money spent in raising the personal comfort of the population saves the outlay which would otherwise be necessary to pay for the hospital treatment of patients belonging to the class in question. Not only have diseases of the respiratory organs been diminished considerably, but also the mortality of children has fallen by 31 per cent., showing the value of fresh air and light in the maintenance of health. Another colony with accommodation for 600 families is now in course of construction, since the results are so very favourable.

Annual Meeting of the Society of German Neurologists.

The German neurologists held their annual meeting in Vienna this year and on the two days (Sept. 17th and 18th) which it occupied a great amount of useful scientific work was accomplished. Professor Erb and Professor Oppenheim were presidents and a large number of eminent neurologists from German-speaking countries were present. Among the papers that were read one on Poliomyelitis attracted unusual attention, as there has been an epidemic of this disease in nearly all parts of Austria within the last two years. The wealth of clinical material at the disposal of the Vienna neurologists and the excellent papers contributed by them were duly appreciated by the guests from abroad, who for their own part had also much to communicate.

Reorganisation of the Chief Board of Health.

The Oberste Sanitätsrath, or chief board of health in this country, has by an ordinance of the Minister of the Interior, or Home Secretary, now received its final constitution and will in future consist of the heads of the medical faculties in Austria, a number of eminent medical and technical and agricultural specialists, and numerous well-known general practitioners. The main intention of the reform is to enable this body to deal in a thorough manner with all questions arising in connexion with public health.

As all arrangements pertaining to social hygiene, to
dwellings, to the care of children, and to the protection of the working classes have been brought within the scope of this organisation, there has been formed amongst the members a series of special committees which, after coming to an understanding as regards any given question, will offer their opinion to the President of the Sanitätsrath. A very welcome feature of the new body is the large number of general practitioners connected with it; about 25 per cent. of the members belong to this class. For this reason the medical profession will in future be able to make its voice better heard than has hitherto been the case. The office of a member of the Oberste Sanitätsrath is an honorary one. The eligibility of general practitioners for membership is the result of the agitation carried on by the medical organisation for economical progress and has created great satisfaction in all medical circles.

BUDAPEST.

(FROM OUR OWN CORRESPONDENT.)

Music in the Treatment of the Insane.

"BETTER than barrels of medicine and much more effective than straps or strait-jackets." These words of Dr. Podstata are the motto of Dr. Berkes, general superintendent of the asylum for the insane at Gyula, and he recently expressed himself to this effect after observing for two hours the effect of music upon an audience composed of insane male and female patients. The concert given for the inmates of the Gyula asylum was more pretentious than any previous entertainment there. Of the 600 patients under the charge

of Dr. Berkes, 200 were assembled in the large hall of the institution and sat there paying more attention than many an audience of persons supposed to be possessed of their full mental faculties. Many of the listeners came from the wards set apart for violent patients; they were constantly under the watchful eyes of the attendants, but none of them gave any cause for anxiety. From the moment of the first number of the programme until the conclusion the audience sat in a state of eager attention and vocifer-ously applauded each selection. Patients who in their wards are continuously restless, muttering, and gesticulating sat quiet and subdued. One patient known to be violent made no more serious demonstration than to rise and move his lips at each outburst of applause. A few of the dull faces did not respond to the charm of the music, but these were rare, and the features of most of the listeners plainly displayed interest and admiration.

Sanitation on the Hungarian Railways.

At the last meeting of the Sanitary Board of the State Railways the executive officer was instructed to draw up certain rules and regulations regarding car sanitation, these to be considered in conference with various railway officials and reported upon at the next regular meeting of the board. In carrying out its inquiry four points are emphasised by the Sanitary Board—namely, (1) a sufficient amount of fresh air properly distributed; (2) cleanliness of the car and its contents, including closets; (3) the proper heating of the car; and (4) overcrowding. The board also inquires whether the above points have received sufficient consideration from the private companies owning railways in Hungary, and the question is asked whether the board shall undertake to secure better sanitary conditions by formulating certain regulations. Circular letters have been sent out to a number of leading medical men, and the character of the replies will influence the board in its decision.

War upon Flies and other Insects.

At a recent meeting of the Nagyvarad Board of Health the following resolutions were adopted:—

Resolved, that the chief inspectors of nuisances, milk, meat, and cattle are hereby directed to visit all retail dealers exposing for sale in front of their premises meat, fish, vegetables, fruit, confectionery, and cake, and to instruct the proprietors that covering of some suitable material must be provided to protect the goods so exposed from files and insects generally.

Resolved, that the chief medical inspector and the chief inspectors of

Resolved, that the chief medical inspector and the chief inspectors of milk, meat, and cattle be and they are hereby directed to instruct their respective subordinates to inspect regularly all manure pits of all stables, whether private or livery, that exist in their districts, and to give instructions to owners or keepers thereof that stables and manure pits must be kept in a clean condition, and where the pit is on the exterior of the premises it must be kept tightly closed or screened with gauze. If a stable is connected with the premises an inspection and report must be made. All places designated in the resolutions must be visited by the inspectors, and they have to make a thorough inspection of the establishments referred to therein, as well as direct the owners or agents that they will have to comply with the new regulations.

Oct. 4th.

THE HUNTERIAN SOCIETY.—The Hunterian Society's first lecture of the session will be delivered at the London Institution, Finsbury-circus, on Wednesday, Oct. 13th, at 8.30 P.M., by Dr. Sidney Martin, on "Certain Infective Processes in the Intestine, their Results and Treatment." All members of the profession are invited to attend.

LITERARY INTELLIGENCE.—Messrs. Baillière, Tindall, and Cox announce that they have ready for immediate publication a new edition of Jellett's "Manual of Midwifery," which forms one volume of the excellent "University Series" published by the firm. The manual has been for the most part rewritten and many new and original illustrations have been added.—Amongst the works issued by the Hungarian Ministries on the occasion of the recent Sixteenth International Medical Congress is a book on the "Protection of Children" which will be issued in the course of the next month. This will be edited by Zoltán Bosnyák and the Count Leopold Edelsheim-Gyulay; it will consist of four parts, dealing with the Forsaken Child, the Hungarian System of State Protection for Children, the similar work of the Child Protection Society, and the subject of Culprits of Minor Age respectively. The preface has been written by Minister Count Julius Andrássy. Members of the Congress will receive this work with the second part of the Proceedings of the Congress.

Obituary.

SIR THOMAS SMITH, BART., K.C.V.O., F.R.C.S. ENG., HONORARY SERJEANT-SURGEON TO H.M. THE KING; CONSULTING SUR-GEON TO ST. BARTHOLOMEW'S HOSPITAL AND THE HOSPITAL FOR SICK CHILDREN, GREAT ORMOND-STREET, W.C.

"Sir Thomas Smith is dead, and in him we have lost not only a great surgeon, but a king among men. We add up all the honours that he received, and all that he did for the advancement of surgery; and we still find ourselves thinking not of them but of him, the sight of his face, the sound of his voice, the happiness of his presence, the help of his good example. He was like St. Luke, 'the beloved': and there is nobody left in our profession able to take his place." Thus writes one of Sir Thomas Smith's pupils and friends, to whom we owe most of this obituary notice, and the words will strike all those who knew the subject of the memoir as quite apposite.

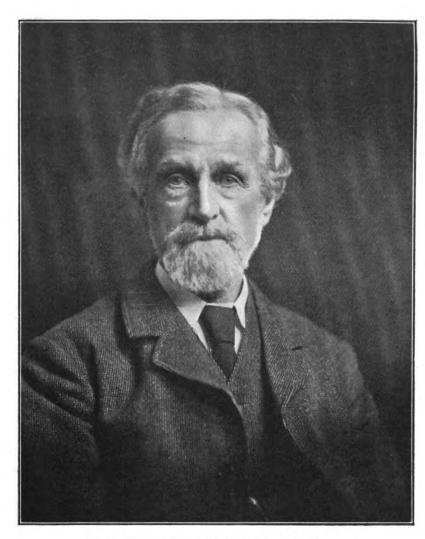

Sir Thomas Smith was born on March 23rd, 1833. His father was Mr. Benjamin Smith, of Great Lodge, Kent. Of his many brothers and sisters, one outlives him, Canon Maberly Smith, Rural Dean of Rochester. He was educated at Tonbridge School. About the time that he left school, his father died. He entered St. Bartholomew's Hospital in 1850; he was apprenticed to Mr. (Sir James) Paget, and was one of the last of the apprentices at the hospital. Other new students, that year, were Sir William Turner, Sir Jonathan Hutchinson, Dr. Hack Tuke, Mr. Bickersteth, and Mr. F. A. Humphry. In 1854, he obtained the Membership, and in 1858 the Fellowship, of the Royal College of Surgeons of England. In 1859, he published his "Manual of Operative Surgery on the Dead Body," illustrated with woodcuts from photographs taken from the body during the operations: it is an admirable book, and was greatly needed, for the examination boards were beginning to require the practice of these operations as a part of medical education. (A second edition of the book, by the help of Mr. Walsham, was published in 1876.)

In 1862 he married a daughter of Mr. Frederick Parbury, of Lancaster-gate. From 1862 to 1868, they lived at 7, Montagu-street, Russell-square. In 1868, they moved house to 5, Stratford-place. It was a venturesome move, for Stratford-place, 40 years ago, was not a "medical street": but, in the later years of his life, Sir Thomas Smith might have said, as Sir James Paget said of Harewood-place, that he had taught the London cabmen to find the street where he lived. For many years, he assisted Sir James Paget in private practice, and was, then and always, like a son to him. In 1879, came the death of his wife. She died after a few days' illness, leaving him with nine children. At St. Bartholomew's Hospital, he was for many years a demonstrator of anatomy and operative surgery: and, on Reb. 24th, 1864, was appointed an assistant surgeon. On July 11th, 1871, he was appointed lecturer on descriptive anatomy, conjointly with Mr. Callender. On Jan. 22nd, 1873, he became surgeon. On July 10th, 1879, he resigned his lectureship in anatomy. On March 10th, 1898, he resigned his surgeoncy: and was appointed to be honorary consulting surgeon, and a governor of the hospital. At the Great Ormond-street Hospital for Sick Children, where he had been a house surgeon in 1854, he was appointed assistant surgeon in September 1861, and surgeon in June 1868. He resigned his surgeoncy in November 1883, and was appointed consulting surgeon. He was consulting surgeon, also, to King Edward VII. Hospital, and to the Alexandra Hospital for Diseases of the Hip. By his death THE LANCET Relief Fund loses its honorary auditor, Sir Thomas Smith having succeeded Sir Henry Pitman in the office. Though discharging the duties for a short time only, he showed keen interest in the work of the Fund, and brought a keen business instinct to bear upon it.

From 1880 to 1900, he was a member of the Council of the Royal College of Surgeons: and was a Vice-President in 1887-8 and 1890-1. In 1900, he was appointed a Trustee of the Hunterian Collection, but he is understood not to have desired to be made President of the College. In 1895, on the death of Sir William Savory, he was appointed Surgeon Extraordinary to H.M. Queen Victoria. He attended many honour of a baronetcy. On the King's Accession, he was appointed Surgeon in Ordinary to His Majesty. In 1901, he In 1901, he assisted Sir Frederick Treves in the operation on the King, and was appointed Honorary Serjeant-Surgeon to His Majesty, and Knight Commander of the Victorian Order.

His writings on surgical subjects show clearly his greatness, his originality, and his wonderful mastery of the facts of each case. It is of no use to wish that he had written more: he had no great liking for long formal text-books. "It's the men who don't get the cases," he once said, "who write the books about them." But there is the making of more than one book in some of his short papers. They stand out, in a very remarkable way, in the old volumes of the transactions of this or that society. In 1868, his paper, "On the Cure of Cleft Palate by Operation on Children," was read before the Royal Medical and Chirurgical Society: it makes a landmark in the history of that operation. To assist him over a bad cleft palate, was to get a lesson in surgery not soon to be forgotten. In 1869, his paper was read, before the same society, proposing "Nephrotomy as a Means of Treating Renal Calculus." It illustrates what we mean by the phrase "a born surgeon." He had not performed the operation: he could find no account of it, except that a certain "Dominicus de Marchetti, a physician of Padua," had once done it: still, he believed that the operation might be safely done. "I owe the Society an apology," he says, "for bringing before it a paper on a some-what novel method of treatment, without, at the same time, detailing some experience of the proceeding the paper discusses. Having, however, waited in vain for more than two years for an opportunity of putting the operation of nephrotomy to the test of experience, I am induced to publish the following short and incomplete com-He gives the most exact rules for the operamunication. tion: he discusses carefully every possible danger: he foresees everything. Especially, he says, the operation must not be attempted till it has been done on the body of one who has died with a stone in the kidney. "I hope that this experience may shortly be forthcoming, either by others performing the operation themselves on patients who may have died with renal calculus, or by the kindness of some surgeon giving me an opportunity of operating under similar circumstances." In 1870 he operating under similar circumstances. In 1970 he brought before the Clinical Society one of the very first cases of vaccino-syphilis recorded in this country. In 1872, he reported to the same society a case of gastrostomy for cancer of the cosophagus: the seventh case thus treated in this country. In 1876, he read before the Pathological Society the first recorded case, in this country, of scurvy-rickets. These five short papers should be carefully studied: they were of more value than many which are ten times longer. Though we may wish that he had written more, yet there was, perhaps, no man in our profession who taught He never accepted the presidency of any of the societies; but he often spoke at the meetings, and always men loved to hear him, for it was impossible not to feel that the man himself was greater than the greatest of his works.

He was curiously like Ambroise Paré. Thanks to le Paulmier, and to Paré's own writings, we know Paré well: and the likeness between the two men, though more than 300 years are between them, is wonderfully close. same directness or simplicity of purpose, the same independence, the same way of "treating not the disease but the patient": in these, and in many other aspects, the two lives reflect the same light. In operating, and in the general management of his cases, Sir Thomas Smith rather distrusted complex and elaborate methods and apparatus, and preferred the exact use of all that he had proved good by long experience: but he was so ingenious, so quick in finding resources and adaptations, that nothing of his work was ever old fashioned. He neither approved of novelties, nor disapproved of them; he went to Edinburgh, to study Listerism for himself, and was the first to employ the Listerian method in St. Bartholomew's Hospital; and he gave careful thought to every proposed new operation: but always with his mind set on the patient, no less than on the operation. "Of all that one remembers of him," writes his pupil and friend, "nothing is more vivid than his passionate desire to do the right thing for the patient. And, by that, I mean not only that he gave profound attention to every point of the members of the Royal Family, and in 1897 received the treatment, and watched very gravely the course of the case,

SIR THOMAS SMITH, BART., K.C.V.O., HONORARY SERJEANT-SURGEON TO H.M. THE KING.

, . . •

and made frequent use of consultation with his colleagues, and weighed the pros and cons of every major operation: but he also gave to his hospital patients immeasurable sympathy. To go round the wards with him, was to learn his compassion and humility. It was no bedside manner; he had no other manner; it came natural to him, if one may call such gifts natural: he would just sit by the bed, and take the patient's hand, and the thing was done, in a moment, absolutely perfect. There never was, nor ever will be, more gentleness, more pity, given to hospital patients. He was compassionate, not with any superficial sentiment, but with emotion: he was 'moved to pity.' He despised, of course, all solemnity, book-learning, theorising, and guessing. If he did not know what was the matter with a patient, he said so, and rather enjoyed saying it. 'The more you see of these cases,' he once said, of acute abdominal cases, 'the less you know about them.' At the weekly consultations at the hospital, he was inclined rather to be silent than to speak, if he found his colleagues talking vaguely. His clinical lectures were short, vivid, personal: and they were, assuredly, among the most original and memorable lectures ever heard at the hospital. He had no equal in the art of putting a case in plain well-chosen direct words: he made you feel the human side of practice, the responsibilities of surgery, the patient's risk, the anxiety of the day's work, the happiness of saving a life. He got students to see what grave and urgent affairs were waiting for them, so soon as they were qualified: he taught them the habit of thinking of operations as patients think of them.

"I had the honour of assisting him, for many years, in his private practice. What he was to the poor, that he was to the rich. I do not mean that he ignored, or pretended to ignore, the difference between ranks: he was far above that. I mean that he was so kind, so sympathetic, to the poor, that he could not be kinder, nor more sympathetic, to the grand people. Whether his patients came from Leather-lane, or lived in Park-lane, it was all one to him, one way of going about doing good. Wherever he happened to be, virtue went out of him. That was part of his profound influence: he saw straight into the hidden life. He understood men and women, as if he had created them: and all their little secrets were bare, when he looked into their hearts. 'He saw life steadily, and saw it whole'; without sentimentality, and without illusions: for he had gone through the valley of the shadow of death, and could enjoy the relief of laughter. And, of course, many of us think of him chiefly because of his delightful humour, his wit, his fanciful talk, his irony, his inimitable way of wrapping up wisdom in chaff. To hear him talk, at a dinner-party, was like the sudden coming out of a stuffy room into the open air, with the wind in your face and the sound of the sea in your ears. He alone could have summed-up another great surgeon thus: 'the mildest-looking man that ever scuttled a ship.' He alone could have said, of an eminent surgeon's son, that he was born with a silver director in his mouth.' But what is the good of remembering two jests out of ten thousand? Only, they who did not know the tragedy of his life, missed the whole beauty of its comedy. It is not too much to say, that he never recovered from the grief of his wife's doubt. death. For all the love that his children have given him, he was still longing for her love: and, for all the crowd of us who were proud to be his friends, he was lonely. He carried his loss about with him for thirty years: it is in every line of his face. That is what set his laughter and his humour so high above the complacent smiles and measured witticism of lesser men. He had come out of such grief as nearly killed him, and he has taken the scars of it to his Yet, so great was his humanity, so inexhaustible his sympathy, that he seemed, always, in love with life. And, indeed, so he was. For he heartily enjoyed a holiday: he was a keen fisherman, he delighted in a day's shooting, in half-a-day's golf, in a game of bridge. He enjoyed, in short, ordinary amusements, though they were now and again wearisome to him: and, wherever he went, happiness came with him."

Till a few months ago, Sir Thomas Smith seemed in good health. Then, he began to lose strength, and was compelled, by the weakness of the heart, to resign all work, and to be an invalid. He was attended, in his last illness, by his son-in-law, Dr. Garrod. He had little pain, and no great distress of breathing: and he died, in his sleep, on Friday, Oct. 1st. He is succeeded in the baronetoy by his eldest son, Mr.

T. Rudolph Hampden Smith, F.R.C.S., of Stockton. His body was buried, on Wednesday, in the Finchley Cemetery: the funeral service was read by the Bishop of Oxford. A memorial service held, at the same time. in St. Mark's, North Audley-street, was conducted by the Dean of Salisbury, assisted by the Rev. H. J. Watters. His Majesty the King was represented by Sir Frederick Treves, and there was a large attendance of relatives and friends, including Sir Richard Douglas Powell, President of the Royal College of Physicians of London, and Mr. Butlin, President of the Royal College of Surgeons of England.

DEATHS OF EMINENT FOREIGN MEDICAL MEN.—The deaths of the following eminent foreign medical men are announced:—Dr. J. Cartellieri, who effected many discoveries of ancient pile dwellings in Bohemia.—Dr. Alber H. Marvin, lecturer on rhinology in the Cleveland College of Physicians and Surgeons.—Dr. Henry C. Chapmay, formerly professor of forensic medicine in the Jefferson Medical College, Philadelphia.—Dr. E. A. Chevassu, inspecting medical officer in the French army.

Medical News.

Examining Board in England by the Royal COLLEGES OF PHYSICIANS OF LONDON AND SURGEONS OF England.—At the First Professional Examination of the Examining Board in England held on Sept. 28th, 29th, 30th, and Oct. 1st, the following gentlemen were approved in the undermentioned subjects :-

Chemistry and Physics.—Cecil Bluett, Sydney University and London Hospital; Ernest Richard Gordon Greville, Birkbeck College; Leon Kahan, London Hospital; John Lyon, London Hospital; Kenneth Holl McMillan, St. Thomas's Hospital; Pierre Joseph François Louis Rathler du Vergé, Guy's Hospital; and Hugh Gordon Sparrow,

Holl McMillan, St. Hollas Hospital; and Hugh Gordon Sparrow, King's College.

Chemistry.—Alma Percy Ford, London Hospital; Arthur Causton Freeth, St. Mary's Hospital; Frank Sykes, Leeds University; Arthur Geoffrey Turner, St. Bartholomew's Hospital; Algernon Randolph Upton, St. Bartholomew's Hospital; George William Watson, Leeds University; and Kim Glen Wee, St. Thomas's Hospital and University College.

Physics.—Hallowes Lloyd Addison, King's College; Paulin Rogar Chevreau, Guy's Hospital; Basil Anderson Cooke, Sheffield University; Thomas Sacheverell Greenaway, Westminster Hospital and King's College; John Casper Münch, London Hospital; and Henry John Hugh Symons, King's College.

Biology.—William Thomas Bell, University College; Edward Henry Brien, Liverpool University, Alma Percy Ford, London Hospital; Harold Percy Gabb, University College; Stanley Victor Percy Pill, St. Mary's Hospital; Sydney William Gardiner Ratcliff, Birkbek College; Khan Sahib, Bombay University; William Henry Arthur Douglas Sutton, Guy's Hospital; Frank Sykes, Leeds University; Oscar Ramsay Unger, University College; and George William Watson, Leeds University.

ROYAL COLLEGE OF SURGEONS OF ENGLAND.—

ROYAL COLLEGE OF SURGEONS OF ENGLAND. At the Preliminary Science Examination for the Licence in Dental Surgery of the Royal College of Surgeons the following gentlemen were approved in the subjects indicated

chemistry and Physics.—Sidney Adams, City of London College; Francis Edward Stuart Brailsford, Charing Cross Hospital; Harold Bridgewater Bramley, Liverpool University; Arthur Caspar Stevenson, Cottam, Charing Cross Hospital; Richard Cowell, University College, Bangor; Robert Lister Donn, Guy's Hospital; Francis Arthur Everett, Charing Cross Hospital; John Stanley Frank Horton, Polytechnic Institute; Ernest Victor Jones, Charing Cross Hospital; Percy King, Technical College, Pottsmouth; Lancelot Turtle Montgomery, Guy's Hospital; and Frank Bedford Stradling, Technical School, Gloucester.

Chemistry—Frank Lodge, Municipal Technical School, Halifax.

Physics.—Aurelius Percy Kincald-Smith, Charing Cross Hospital; and Roy Oswald Shilton, Birmingham University.

UNIVERSITY OF CAMBRIDGE.—The following appointments have been made:—Demonstrator of Comparative Anatomy: F. A. Potts, M.A., Trinity Hall. Demonstrator of Animal Morphology: L. A. Borradaile, Demonstrator of Annual morphology. In Property of Chemistry: F. W. Dootson, M.A., Trinity Hall. Senior Demonstrator of Botany: F. T. Brookes, M.A., Emmanuel College. Junior Demonstrator of Botany: D. Thoday, M.A., Trinity College. -The following have passed the Examination in Tropical Medicine and Hygiene:

P. H. Bahr, Trinity; C. S. Bowle-Evans, Emmanuel; J. C. Kennedy; J. L. Lanham; and H. Macfarlane.

University of Glasgow.—The following have ssed the first professional examination for the degrees of Bachelor of Medicine (M.B.) and Bachelor of Surgery (Ch.B.) in the subjects indicated (B., Botany; Z., Zoology; P., Physics; and C., Chemistry):—

Bachelor of Medicine (M.B.) and Bachelor of Surgery (Ch.B.) in the subjects indicated (B., Botany; Z., Zoology; P., Physics; and C., Chemistry):—

Robert Armstrong (B., P.), George Plett Barr (B., P.), Andrew Duffield Blakely (P.), Abraham Blashky (B.), William Branest Boyd (B., P.), Robert William Brander (B., P.), William Adam Brechin (B., P.), David Peebles Brown (B., P.), William Hunter Brown (B., P.), David Peebles Brown (B., P.), William Hunter Brown (B., P.), David Peebles Brown (B., P.), William Hunter Brown (B., P.), William Brander Graname Buchanan (E., James Wilson Burton (C.), James Campbell (B., P.), William Loonard Cassells (C.), James Campbell (B., P.), William Loonard Cassells (C.), James Grander (B., P.), William Conley, M.A. (B., P.), George Gibson Cooper (B., Z.), Thomas Mulr Crawford (B., P.), Nathaniel Crichlow (B., P.), Lawrence Cromble (B., Z., P.), Gabriel Daniel de Kock (Z., C.), William Donald (P.), Thomas Ingram Dun (P.), Thomas Ferguson (B., P.), James Bryan Fotheringham (Z.), James Fraser (P.), Ian Grant (B., P.), Robert Masson Greig (B., P.), William John Henry (B., P.), George Hislop (B., P.), William Hornsby (B., P.), Thomas Cameron Houston (Z.), John Ferguson Hutton, M.A. (B., Z., C.), David Johnston (B., P.), John Finlayon Lang, M.A. (B.), Alexander Lindssy (P.), Carel Johannes van Lingen (Z., P.), Reginald Lyon (Z.), Douglas M'Alpine (Z., P.), Daniel Steel M'Bean (B., P.), John Bowes M'Dougall (B., P.), John Molie (C.), John Maclinnes (B., P.), Charles Robertson Milntosh (B., P.), Robert Hugh M'Killop (C.), Donald Mackinnon (B., Z., P., C.), James Robertson (Cowper Mackintosh (B., P.), Kenneth Norman MacLean (B., Z., P.), William (B., P.), Robert M'Lean (B., P.), Neil Macleod (P.), Freierick William M'Millan (B., P.), Robert Martin M Millian (B., P.), Robert Milliam Martin (B.), William Luddington Peacock (B., P.), Alexander Dryden Mortat (B., P.), William Luddington Peacock (B., P.), Alexander Robertson (B., P.), Stuart Robertson (B., P.), Stuart Robertson (B., P.), Stuart Ro

The following have passed the Second Professional Examination for the degrees of Bachelor of Medicine (M.B.) and Bachelor of Surgery (Ch.B.) in the subjects indicated (A., Anatomy; P., Physiology; and M., Materia Medica and Therapeutics):---

Anatomy; P., Physiology; and M., Materia Medica and Therapeutics):—

Mark James Aitken (A., M.), James Browning Alexander (A.), John Campbell Hill Allan (A., P., M.), James Wallace Anderson (A.), Alexander John Archibald (A.), Charles Averill (M.), Archibald MacAllister Blackwood (M.), Simon Harry Bloom (P., M.), John Bower (A.), David Sands Brough (A., M.), James Turner Brown (M.), Robert Archibald Brown (M.), William Murdoch Buchanan (A.), George Cochrane, M.A. (A.), Robert Corbett Corbett (A.), Alexander Moffat Dunlop (A.), Walter Elliot Elliot (P.), Philip Figdor (P.), James Findlay, M.A. (A.), Robert Findlay (P.), Hugh Forrest (A.), Alexander Fraser (A.), Leander Lowrie Fyfe (A.), Adolph Robert Hanns Geyer (P.), John Gibson (M.), Cecil William Fletcher Groenhill (M.), Andrew Smith Hannay (A.), Alexander Gibson Henderson (A., P., M.), James Hendry, M.A. (M.), Andrew Gray Holms (A.), William Hunter Howat (A.), Felix Arthur Kerr (A., P.), Thomas Joseph Kirk (A.), Alexander Kirkhope (M.), Norman Veitch Lothian (A., P.), Norman M'Farlane (A.), James David Mackinnon (A.), Archibald M'Leod (A.), Murdoch Hugh MacLeod (A., P.), William Wyllie MacNaught (M.), Stephen Anderson MacPhee (A.), George Hanson M'Robert (A., P., M.), Osborne Henry Mavor (P., M.), Stuart Spence Meighan (M.), Andrew Mulr (P.), Arthur Alexander Murlson (P.), Andrew Nellson (M.), Hugh Paterson (A.), Henry Charles Deans Rankin (A., M.), Hugh Young Riddle (A.), James Gordon M'Gregor Robertson (M.), John Livingstone Scott (P.), William Logan Scott (A.), William Sneddon (A.), Roderick Alexander Steven (A.), John Alexander Stewart (P.), Lawrence Tweedie Stewart (A.), Edward Napler Thomson (A.), Archibald Wilson (P.), and Douglas Wilson (M.).

Women.—Isabel Inglis (A., M.), Katherine Stewart MacPhail (M.), Lucy MacBean Ross (A., P.), Christina Hamilton Shearer (A., M.), and Isabel Jane Stark (P.).

The following have passed the third professional examination for the degrees of Bachelor of Medicine (M.B.) and Bachelor of Surgery (Ch,B.) in the subjects indicated (P., Board led to the adoption of the present hospital. The total

The following passed with distinction in the subjects

The following passed with distinction in the subjects indicated:-FIRST EXAMINATION.

Botany.—Robert Horatio Williamson and Marguerite Wilson.

Physics.—John Bowes M'Dougail, James Robertson Cowper Mackintosh, Thomas Murray Newton, Stanley Robertson, Stuart Robertson, Marion Thompson, Sarah Adam Watson, and Joseph Bannister Williamson. Chemistry.—John Sillars.

THIRD EXAMINATION.

Medical Jurisprudence and Public Health.—Thomas Jones Mackie and James Lachlan Ure.

Foreign University Intelligence. Bologna: Dr. Bernardino Lunghetti has been recognised as privat-docent of Anatomy.—Breslau: Dr. Georg Lenz has been recognised as privat-docent of Ophthalmology.— Bucharest: Dr. Stanculeanu has been appointed Professor of Ophthalmology. Dr. Kubinyi has been recognised as privat-docent of Midwifery.—Buffalo: Dr. Robert F. Sheehan has been appointed Professor of Hygiene, in succession to Dr. Henry R. Hopkins, resigned.—Chicago (Northwestern University): Dr. J. A. Abt, of the Rush Medical College, has been appointed Extraordinary Professor of Children's Diseases.—Cornell (New York): Dr. William B. Dr. Kubinyi has been recognised as Coley, Lecturer in the College of Physicians and Surgeons, New York, has been appointed Professor of Surgery.— Florence: Dr. Ferruccio Schupfer has been promoted to the Ordinary Professorship of Internal Pathology. - Freiburg: Dr. B. Salge of Göttingen has been appointed Extraordinary Professor of Children's Diseases.—Genoa: Dr. Aldo Fabris has been appointed Extraordinary Professor of Pathological Anatomy.—Harvard: Dr. Elmer E. Southward has been appointed to the chair of Neurology, Dr. Myles Standish to the chair of Ophthalmology, and Dr. Milton J. Rosenau to that of Hygiene and Preventive Medicine.— Pisa: Dr. Giuseppe Tusini has been appointed Extraordinary Professor of External Pathology.—Prague (German University): Dr. Karl Walko, privat-docent of Medicine, has been granted the title of Extraordinary Professor.—Rome: Dr. L. Concetti has been promoted to the Professorship of Children's Diseases.—Tübingen: Dr. Alfred Busch has been recognised as privat-docent of Psychiatry. Würzburg: Dr. Gerhard Hotz has been recognised as privatdocent of Surgery.

KING EDWARD'S HOSPITAL FUND FOR LONDON. Amongst the latest contributions received at the Bank of England for King Edward's Hospital Fund for London are the following: Annual subscriptions—Alderman Sir W. Vaughan Morgan, Bart., £50; Rev. A. W. Davies, £25; Messrs. Tattersalls, £25. Donations—Mr. C. W. Drabble, £105; Home and Colonial Stores, Limited, £26 5s.

Worthing Isolation Hospital.—The borough of Worthing now possesses a good modern isolation hospital, which was formally opened on Sept. 29th. Situate at Swandean, the site is in every way excellent for such an establishment. For a good many years there has been accommodation there for infectious cases, but under cramped conditions of space it has been found exceedingly difficult to isolate different kinds of cases. The erection of two ward pavilions allows accommodation for 32 patients in all, and one ward is to be set apart for diphtheria and the other for scarlet fever. Originally the idea was to erect one pavilion for 14 beds, but consultation with the Local Government cost, together with the necessary land, has been £10,000, and this provision should meet the requirements of the borough for many years.

THE GUILD OF ST. LUKE.—The annual meeting and festival of the Birmingham Ward will be held on Wednesday, Oct. 27th, at 8 P.M., at Holy Trinity Church, Coventry, when the festival sermon will be preached by the Lord Bishop of Worcester. All medical practitioners in the district are invited to attend.

INSTITUTE OF HYGIENE.—The progress of the Midland Counties branch during the two years of its existence has been so encouraging that it has been thought wise to acquire a hall to provide accommodation for the delivery of lectures, the holding of examinations, and especially for the establishment of a permanent exhibition of hygienic products. This exhibition was opened last week by Sir William Bennett.

THE SALISBURY INFIRMARY.—The 142nd anniversary service of Salisbury Infirmary was held at the Salisbury Cathedral on Sept. 28th. The members of the corporation, wearing their robes of office, joined the procession from the infirmary, which included the Earl of Pembroke (visitor to the institution), Earl Radnor (the President), the court of governors, and the medical staff. The sermon was preached by the Dean, Dr. Page Roberts.

Ptomaine Poisoning from Shrimps.—After partaking of some shrimps purchased from a street vendor at Shoreham (Sussex) a little girl of six years was seized with abdominal pains and died within a very short time. At the inquest on Sept. 29th Dr. W. A. Kinloch said that death was due to exhaustion following ptomaine poisoning, and a verdict was returned accordingly. The jury added a rider calling the attention of the urban council to the hawking and selling of food which was unfit for consumption, and the coroner, Mr. F. W. Butler, said that he would bring the matter before the notice of the police.

THE HOSPICE OF THE LITTLE ST. BERNARD.—
The Order of St. Maurice, to which the hospice belongs, in view of the increasing numbers of well-to-do visitors of all nationalities who pass the night at it, has decided to charge from 3 fr. to 5 fr. for the use of a room and 2 fr. 50 c. for board per diem. This decision it has come to in the interests of the many humble and needy wayfarers for whom the hospice was primarily founded, and who not seldom have been "crowded out" by others well able to pay for the accommodation and the nourriture they have hitherto been not above accepting gratuitously.

University of London.-A course of eight lectures on "Recent Researches on Chloroform Anæsthesia" will be given during the first term of the present session by Professor G. A. Buckmaster and Mr. J. A. Gardner in the Physiological Laboratory of the University on Tuesdays at 5 P.M., beginning on Oct. 12th. During the second term a course of eight lectures on a subject to be announced will be given by Mr. W. B. Hardy, F.R.S., on Tuesdays at 5 P.M., and during the third term a course of eight lectures on "The Physiology of the Peripheral Nerves" will be given by Dr. N. H. Alcock on Tuesdays at 5 P.M. Details of these courses will be published at a later date. The lectures are addressed to advanced students of the University and to others interested in physiology. All the courses have been recognised as courses of advanced lectures which a candidate at the B.Sc. (honours) examination in physiology may name for part of his practical examination. Any member of a London school of medicine, whether an undergraduate of this University or not, is entitled to a card of admission on application to the academic registrar. In addition a course of eight lectures on "Recent Advances in the Physiology of Digestion," by Professor E. H. Starling, F.R.S., will be given at University College, on Fridays at 5 P.M., beginning on Oct. 15th; a course of six lectures on "The Pineal and Pituitary Bodies" will be given by Professor A. Dendy, F.R.S., and Professor W. D. Halliburton, F.R.S. at King's College, on Mondays, at 4.30 P.M., beginning on Nov. 1st; and a course of eight the Chief Constituents of Urine" will be given by Dr. E. L. Kennaway and Mr. J. H. Ryffel, at Guy's Hospital, on Thursdays, at 5 P.M., beginning on Oct. 7th. For further

information application should be made to the authorities of the different Colleges.

KING'S COLLEGE (UNIVERSITY OF LONDON).—A public inaugural lecture will be delivered on Oct. 12th, at 4 P.M., by Professor C. A. Barkla, D.Sc., on "Röntgen Rays." The chair will be taken by the Vice-Chancellor of the University of London.

FLAG RANK FOR A NAVAL PHYSICIAN.—Überall, the organ of the German Navy League, announces amongst recent promotions to the rank of rear-admiral in the German navy the name of Dr. Runkwitz, "Naval General Physician," lately principal medical officer of the High Sea Fleet.

St. Bartholomew's Hospital and College (University of London).—The following scholarships have been awarded on the results of a recent examination: (1) senior entrance scholarship in science (value £75), A. G. Evans, B.A., Trinity College, Cambridge; (2) senior entrance scholarship in science (value £75), A. C. Roxburgh, B.A., Trinity College, Cambridge, and G. Sparrow, B.A., Caius College, Cambridge (equal); (3) junior entrance scholarship in science (value £50), P. O. Ellison and D. H. D. Wooderson (equal); (4) entrance scholarship in arts (value £100), C. Cooke, Magdalen College School, Oxford; and (5) Jeaffreson exhibition in arts (value £50), G. C. Linder, Brighton Grammar School.

GUY'S HOSPITAL MEDICAL SCHOOL.—The following entrance scholarships and certificates have been awarded: Senior Science Scholarship for University Students, £50, Trevor Brady Heaton, B.A., Christ Church College, Oxford. Junior Science Scholarships: £150, Charles Hamilton Gould, Preliminary Science Class, Guy's Hospital, and Christchurch, New Zealand; £60, James York Moore, Preliminary Science Class, Guy's Hospital; equal certificates, Allen Noel Minns, Thetford Grammar School, and Cyril Henry Edwards, St. Paul's School, West Kensington, W. Entrance Scholarships in Arts: £100, Henry Francis Thomas Hogben, Bedford Grammar School, and William Morris Lansdale, St. Olave's and St. Saviour's Grammar School, equal; £50, James Kyle, University Tutorial College.

THE HEALTH OF MALTA.—Sir E. M. Merewether. K.C.V.O., C.M.G., Chief Secretary to the Government of Malta, reporting on the Blue-book of the colony for 1908-09, Malta, reporting on the Blue-book of the colony for 1908-09, states that the estimated population on April 1st this year was 212,888, an increase of 2914 on the previous year. The birth-rate in 1908-09 was 38-22 per 1000, as compared with 39.57 per 1000 in 1907-08. The death-rate of the civil population in 1908-09 was 23.4 per 1000, as against 23.09 per 1000 in the previous year. The general state of the public health was on the whole good. There were 471 case of Mediterranean fever with 50 deaths, as against 520. of Mediterranean fever, with 50 deaths, as against 520 cases, with 45 deaths, in the previous year. There were only eight cases in the fleet and garrison, none of which proved fatal. In the Central (Civil) Hospital the use of unboiled milk has been discontinued since 1907-08, and a remarkable diminution in the number of cases contracted in that institution has been the result. The number of cases of Mediterranean fever contracted in the Civil Hospital in 1905-06 and 1906-07 was 23 and 11 respectively, while only five cases were reported in 1907-08 and none at all in 1908-09. In May, 1908, a committee was appointed to consider the steps to be taken for the suppression of Mediterranean fever among the civil population, the report of which was received in January last. Regulations were drawn up on the general lines indicated by the committee and were brought into force on July 1st, 1909. There was a considerable abatement in the measles epidemic, but there was a serious epidemic of influenza, 440 cases with 16 deaths being reported. All but one of the 23 deaths from diphtheria occurred among the civil population. The percentage of deaths to the number of cases was 15.6, as against 23.3 in 1907-08 and 32.2 in 1906-07. Owing to the ignorance or carelessness of parents in feeding and nursing their infants, infant mortality continues to be excessive. The infants, infant mortality continues to be excessive. number of deaths which occurred among children under 12 months was 1824, or 224 per 1000 births, while the number of those who died before reaching the age of five years was 2569, or 316.57 per 1000 births. For the reason given,

enteritis is the disease which causes the greatest number of deaths amongst infants, the total number of children who have died of that disease in the past ten years being 10,347.

ROYAL COLLEGE OF SURGEONS OF ENGLAND: MUSEUM DEMONSTRATIONS.—The following demonstrations of specimens in the Museum will be given in the theatre of the College in Lincoln's Inn-fields for medical practitioners and advanced students by Professor Arthur Keith and Professor S. G. Shattock alternately:—Oct. 15th, 5 P.M. (Professor Keith): Specimens illustrating Various Forms of Constrictions and Occlusions found in the Course of the Alimentary Canal. Oct. 18th, 5 P.M. (Professor Shattock): Osteoma. Oct. 22nd, 5 P.M.: Specimens illustrating Various Forms of Congenital and Acquired Diverticula of the Alimentary Canal. Oct. 25th, 5 P.M.: Adenoma and Papilloma. Parliamentary Intelligence.

NOTES ON CURRENT TOPICS.

The Parliamentary Session.

THE Parliamentary session, it now seems probable, will extend into the middle of November. If the majority of the peers carry out the intention which is more and more freely attributed to them, of refusing to pass the Finance Bill, a General Election is inevitable. This, of course, is the dominating factor in politics at present. If a General Election does become necessary, it will in all probability take place in January rather than at the end of the year.

The Housing and Town Planning Bill.

The House of Lords has considered the Housing and Town Planning Bill on report, but the drastic amendments made in committee remain for the most part. No alteration has been made in Clause 69, which deals with the appointment of county medical officers. In committee two subsections were cut out at the instance of Lord Belper. One of these subsections gave the Local Government Board power by order to prescribe the duties of medical officers of health appointed by a county council. The other rendered these medical officers irremoveable except with the consent of the Local Government Board. No attempt was made to reintroduce these provisions, and accordingly the Bill now goes forward for third reading without them. The Lords occasionally exercise the privilege of amending a Bill on third reading, but after their attitude in committee on these points any revision of the text of the clause as it now stands is quite improbable.

HOUSE OF LORDS.

MONDAY, OCT. 4TH.

District Medical Officers of Health.

During the consideration on report of the Housing and Town Planning Bill,
The Earl of HARROWBY moved to amend Clause 69 (appointment of

The Earl of Harrowby moved to amend Clause 69 (appointment of medical officer by county council) by introducing into it the following subsection: "A medical officer of health of a district who is not in private practice shall not be appointed for a limited period only and shall be removeable by the electing authority with the consent of the Local Government Board and not otherwise." He said that the district medical officers of health should have the protection of this provision, which they were anxious to obtain. It was said that the Government intended to bring in a Bill next year to deal with such matters, but the present President of the Local Government Board might not be in office then to bring it in, or there might be no time to deal with it.

Earl BEAUCHAMP (who had charge of the Bill on behalf of the Government) expressed sympathy with the object of the amendment, but deprecated the introduction of such a provision in a clause dealing exclusively with the medical officers of counties. It might be better to take the matter up next session in a Public Health Bill.

The Earl of Harrowby withdrew his amendment.

HOUSE OF COMMONS.

THURSDAY, SEPT. 30TH.

Lavatory Accommodation for Workmen.

Lavalory Accommodation for Workmen.

Mr. Wardle asked the Secretary of State for the Home Department whether his attention had been called to the practice extensively carried on in Germany and America whereby wardrobe and lavatory accommodation was provided for workmen at the place of their employment; and whether, in view of the benefit in public health and cleanliness to be derived from such a practice, he would consider the advisability of securing the extension of the practice in this country.—Mr. Gladstone replied: My attention has been called to this matter and in connexion with mines it has received the consideration of the Royal Commission on Mines. The honourable Member will find their recommendations on the subject in Part XVIII. of the recently issued report. In the case of a number of trades where the conditions of work make the provision of lavatory and cloak-room accommodation especially important for the health of the workpeople, the employer is now required under the Factory Acts to workpeople, the employer is now required under the Factory Acts to

provide it, and in many other cases such accommodation is supplied voluntarily by employers. The report of the chief inspector of factories for 1908 notes, I am glad to say, a growing tendency to provide improved facilities for washing in many districts, and the question is receiving the constant attention of my department.

The Medical Treatment of Suffragist Prisoners.

Mr. Snowden asked the Secretary of State for the Home Department whether he had any information as to the state of health of the women suffragist prisoners and whether they were still being fed by force.—Mr. GLADSTONE answered: I am glad to say that the improvement of the health of all the suffragist prisoners continues. I am not absolutely able to answer the question as to whether they are still fed by force. "Force," however, is hardly the right word to apply, because I understand that although three of them are being fed by the medical officers they are in a sense fed without any resistance on the part of the prisoners. I may say that in no case has the stomach-pump been used. Mr. Snowden: May I ask whether it is not a fact that the women are handcuffed during the time food is being administered?

Mr. GLADSTONE: No, sir; there is no truth whatever in that statement. Mr. Snowden asked the Secretary of State for the Home Department

statement.

Mr. A. Lynch: May I ask why the right honourable gentleman so ostentatiously puts forward the medical aspect of the case, and whether the medical officers in the prison have acted under his instructions and

by his directions?

Mr. Gladstone: I put forward the medical officers in a prominent position because it is a medical question, and a very heavy responsibility

sets upon them.

Mr. Lynch: Is it usual for medical officers to act on the instructions of the right honourable gentleman or on their own initiative in such

Mr. Gladstone: What authority has the honourable Member for saying that I have given instruction to the medical officers? It is the duty of the medical officers to attend to the health of prisoners in their charge and that is precisely what the medical officers have been doing

FRIDAY, OCT. 1ST.

The Medical Treatment of Suffragist Prisoners.

The Medical Treatment of Suffragist Prisoners.

Mr. Keir Hardie asked the Secretary of State for the Home Department whether he had received any report from the medical officer at Winson Green Gaol, Birmingham, detailing the method adopted to administer food by force to the women suffrage prisoners; whether the instrument used was Blandford's casophageal instrument, or whose; whether a screw gag was used to prise the teeth apart and keep the jaws open; whether the prisoners were strapped down, or, if not, how many attendants took part in the operation; and whether he could give the names of the women who had been subjected to this treatment.—Mr. Gladstone wrote in reply: I have received several reports from the medical officer. I find that Blandford's casophageal tube has not been used; in those cases where a tube was required the ordinary soft rubber feeding-tube used in hospitals was employed. No screw gag was used, and the prisoners were not strapped down. The number of attendants present varied from one to five. I do not think it is desirable that I should mention the names of the prisoners. I am satisfied that everything has been done with the utmost gentleness possible in the circumstances, and the prisoners themselves have borne witness to the kindness of the officers.

Monday, Oct. 4TH.

MONDAY, OCT. 4TH.

The Medical Treatment of Suffragist Prisoners.

The Meilical Treatment of Suffragist Prisoners.

Mr. Keir Hardie asked the Secretary of State for the Home Department whether the medical officer of Winson Green Gaol, Birmingham, reported any injury to the teeth, throat, or other parts of the body of those women prisoners who had undergone the special hospital treatment known as administering food by force, and whether the medical officer had said for how long this treatment could be continued without serious injury to the patients.—Mr. MASTERMAN replied (on behalf of Mr. GLADSTONE): The medical officer reports that no injury to the throat, teeth, or other parts of the body has been sustained by any of the prisoners who have undergone the special hospital treatment mentioned in the question. My right honourable friend is advised on good medical authority that no serious injury is to be apprehended in any case of this kind, even if the treatment has to be prolonged for some considerable time. considerable time.

case of this kind, even if the treatment has to be prolonged for some considerable time.

Mr. Kfir Hardif: Has the Home Office seen the report by eminent medical authorities to the effect that this treatment produces permanent injury and very often fatal results?

Mr. Masterman: I have seen no such report.

Mr. Kfir Hardif asked further how often during the past 12 months prisoners in Winson Green Gaol, Birmingham, had had food administered to them by force; whether, in the case of the women suffragists who had undergone this treatment, the operation was performed by the prison doctor or, if not by him, by whom; and what was the method adopted in connexion with the operation.—Mr. Masterman replied: With the exception of these women prisoners there have been no cases in Birmingham Prison during the past 12 months in which it has been accessary to feed any prisoner forcibly. This treatment has been administered in some cases by the medical officer and in other cases by a medical practitioner who has been called in to assist him. The method has been, where practicable, feeding by means of teaspoon or from a feeding cup, but where necessary the soft rubber tube in use in hospitals has been employed.

Mr. Belloc: Has not this been the constant practice in regard to men for many years past?

Mr. Masterman: It has been the constant practice with respect to men and women for many years past.

Mr. MASTERMAN: It has been the constant practice with respect to men and women for many years past.

Mr. Keir Hardle asked whether the Home Secretary had received a petition from the parents or other relatives of some of the women suffragist prisoners in Winson Green Gaol, Birmingham, stating that they were anxious concerning the state of health of the prisoners, and praying to be allowed to send their own medical adviser to report on their condition; and, if so, whether he had been able to so far relax the prison rules as to comply with this request.—Mr. MASTERMAN answered: Applications to the effect indicated have been received, but my right honourable friend has been unable to accede to them. The prisoners mentioned are receiving full and constant attention from the medical officer of the prison, who has been in consultation with the medical authorities of the Home Office at the time when the

refusal to take food made the prisoners' state of health serious, and has had the assistance of a medical man in practice in Birmingham who has been present when food has been administered. According to the latest report received this morning the health of the prisoners continues to improve. Only one of them still refuses to take food without the use of

Meat Inspection.

Mr. Watt asked the President of the Local Government Board whether he was aware that uniformity of standard of meat inspection was enjoined and followed throughout the German Empire; and whether he proposed to adopt a similar course in this country, especially in view of the fact that cities and boroughs which adopted a high standard of inspection were pensilised by the trade being sent elsewhere.

—Mr. Burns replied: I am aware of the system adopted in Germany for securing uniformity of meat inspection. I do not think that it would be practicable to enforce a similar system in this country at the present time; but both by circulars which they have issued and by the inquiries made by its inspectors the Local Government Board has pressed upon local authorities and their officers the importance of uniform and efficient meat inspection. I am happy to say that in the country generally there has been a distinct improvement during the last few years in the qualifications of meat inspectors and the practice of meat inspection.

Tuesday, Oct. 5th.

TUESDAY, OCT. 5TH.

Tuberculosis in the Post Office Service.

Mr. Summerred from his department during the years 1899 to 1908 suffering from tuberculosis; and whether, on their discharge, any provision for the treatment of the disease in a home or hospital was made by his department on their behalf; and whether any money grant was made to such men.—Mr. Buxton replied: The number of established Post Office servants superannuated on account of tuberculosis during the past ten years is as follows:—

		Men.	W	omen.			Men.	Women.		
1899	********	72	•••••	11	1904	•••••	109	•••••	19	
1900		82		11	1905		96		18	
1901	••••••	9 5	•••••	21	1906		101	•••••	15	
1902	*******	76	********	6	1907		81	•••••	15	
1903	********	104	•••••	15	1908	•••••	90	•••••	20	

The established force to which these figures refer numbered in 1908 in round figures 90,000. There is no official arrangement for affording treatment to Post Office servants suffering from tuberculosis. Every established officer retiring on account of ill-health is entitled either to a penaion or a gratuity under the terms of the Superannuation Acts.

Tuberculosis in the Navy.

Tuberculosis in the Navy.

Mr. SUMMERBELL asked the First Lord of the Admiralty to state the number of men discharged from the navy during the years 1899 to 1908 suffering from tuberculosis; whether, on their discharge, any provision for the treatment of the disease in a home or hospital was made by his department on their behalf; and whether any money grant was made to such men.—Mr. McKenna answered: The number of officers and men finally invalided from the service (including marines) for tuberculosis for the years 1899 to 1908 is 2573 made up as follows: 1899, 207; 1900, 185; 1901, 232; 1902, 288; 1903, 354: 1904, 353; 1906, 331; 1906, 214; 1907, 266; 1908, 283. No special provision is made for their treatment on their discharge in a home or hospital. They are paid gratuities or pensions according to their service under the ordinary regulations.

Lead Polassaina in Savanaea.

Lead Poisoning in Swansea.

Mr. Charles Duncan saked the Secretary of State for the Home Department what was the number of cases of lead poisoning during 1908 in the Swansea district in the spelter, lead, and silver works; whether such cases were on the increase; and, if so, whether any additional safeguards were to be introduced with a view to the prevention, as far as possible, of such cases in the future.—Mr. Gladstoner replied: The number of cases in 1908 was 38, as compared with nine in 1907, but in the first eight months of this year there were 24 cases, as compared with 28 in the corresponding period of 1908. A special inquiry had been made by one of the medical inspectors of factories in regard to lead smelting and certain allied industries, and his report, which includes recommendations for further precautions, has just been received and is under consideration.

Dundee Eastern Poorhouse.

Mr. WILKIE asked the Lord Advocate whether his attention had been drawn to the case of attempted suicide in the Dundee Eastern Poorhouse some five months ago; whether he was aware that the committee appointed by the Dundee parish council to inquire into this case expressed dissatisfaction with the investigation of the medical inspector of the Local Government Board; and whether, in view of the above facts and the assertions which had been made against certain officials in the Dundee Eastern poorhouse hospital as to the treatment of patients, he would institute a public inquiry, under the Local Government Board, to investigate into the assertions made.—Mr. Uku repiled: In April last the case of attempted suicide referred to was formally reported to the Local Government Board. The circumstances were at once inquired into by the Board's medical inspector, who, in view of the facts then elicited, formed the opinion that the accident was such as might have occurred in any institution, however well managed. The Board was not able to attach blame to any of the poorhouse staff. Two months after the accident, and a month after the death of the inmate a subcommittee of the parish council was appointed to inquire into certain allegations the accident, and a month after the death of the inmate a subcommittee of the parish council was appointed to inquire into certain allegations affecting the poorhouse administration, and, in particular, the actions of the resident medical officer. It is the case that the subcommittee, in its report of August 11th, expressed the view that the investigation made by the medical inspector into the suicide was not so full as the seriousness of the case required, and held that the resident medical officer was to blame. The facts elicited by the medical inspector and by the evidence taken before the subcommittee leave ground, in the opinion of the Local Government Board, for a legitimate difference of opinion; but on August 24th last the Local Government Board expressed its satisfaction with the adequacy of the subcommittee's inquiry into the various complaints, and, as the resident medical officer had resigned in

June, intimated that it did not propose to hold any supplementary inquiry. As the subcommittee has advanced good reasons for considering that the complaints, so far as substantiated, were all directly or indirectly due to the conduct of the resident medical officer, and, as he has long ago ceased to be a member of the poorhouse staff, the Local Government Board does not propose to reopen the inquiry.

WEDNESDAY, OCT. 6TH.

The Medical Treatment of Suffragist Prisoners.

Wednesday, Oct. 6th.

The Medical Treatment of Suffragist Prisoners.

Mr. Keir Hardie asked the Secretary of State for the Home Department (in the absence of the Prime Minister) whether he had received a memorial signed by Sir Victor Horsley and 116 other medical practitioners pointing out that the compulsory feeding of women prisoners was attended with the gravest risks, that unforeseen accidents were liable to occur, that the subsequent health of the person so treated might be seriously injured, and that, in the opinion of the memorialists, the action was unwise and inhumane, and praying him to use his influence to prevent the continuance of the practice; and whether he is prepared to accede to the prayer of the memorialists.—Mr. Gladstore replied: The memorial has been received. Though the statements it contains are not borne out by the prison medical authorities, whose experience of artificial feeding is necessarily much wider than that of the memorialists. I thought the right to refer the memorial to the President of the Royal College of Physicians of London, and I have this morning received the following letter from Sir Richard Douglas Powell:—"I beg to state that I do not agree with the opinion expressed in the memorial signed by some medical practitioners in protest against the artificial feeding of certain prisoners who refuse to take food in the normal manner. The statements contained in the memorial are inaccurate and greatly exaggerated. The method of artificial feeding is largely employed amongst those who from mental aberration refuse to take nourishment otherwise and also with those who are physically unable to take it. It would be an exaggeration to say that the method of artificial feeding is wholly free from the possibilities of accident with those who forcibly resist, but no such cases have come to my knowledge. Nor can it be said that the method is as convenient or as free from possible digestive allments or discomforts as a reasonable diet taken naturally would be. But it may be remarked th

DEATHS.

MUSEETT.—On August 25th, 1909, at 143, Elizabeth-street, Hyde Park, Sydney, N.S.W., Philip Edward Muskett, L.R.C.P. et L.R.C.S. Edin., aged 52.

POLIOCK.—On Oct. 5th, at Park-street, Grosvenor-square, William Rivers Pollock, M.D. Cantab., F.R.C.P., aged 50 years.

SMITH.—On Oct. 1st, at Stratford-place, W., Sir Thomas Smith, Bart. K.C.V.O., F.R.C.S., Honorary Serjeant-Surgeon to H.M. the King, aged 76 years.

aged 76 years.

N.B.—A fee of 5s. is charged for the Insertion of Notices of Births. Marriages, and Deaths.

Notes, Short Comments, and Answers to Correspondents.

AN INTERNATIONAL COLOUR CHART.

THE Secretary of the Royal Horticultural Society has recently addressed a letter to the press calling attention to the difficulty which his society has felt for many years in describing definitely the colour of any flower "in terms which shall be distinctly and definitely intelligible in New York and Paris, Berlin and Quebec, as in London." After pointing out the difficulty which all must feel who have to represent colour in words, his letter continues:

We determined, therefore, to endeavour to establish an international code by which anyone, anywhere, could convey to anyone else at a distance of time or place exactly and precisely the colour and shade he is speaking of. With this end in view we searched for a good colour chart, and have been successful in finding an excellent one containing 360 colours between white and black, with the name of each in French, German, English, Spanish, and Italian, together with four shades of each of the 360 colours, so that anyone wishing to describe to a friend at Calcutta the exact colour and shade of a flower or a silk or a painting need only refer to the colour chart number, quoting, if for "apricot," e.g., page 53, shade 3; or if for "rosypink," page 118, shade 4; and so on. The cost of production of so beautifully printed and so large a chart was, of course, very heavy, and it was issued at one guinea net, but our society, by adopting it as an international standard, and purchasing a very large number of copies from the publisher, is able to supply it to our Fellows and others at 14s. 6d., or if by post 15s.

Last week we discussed the number of colour shades appreciable by the human eye and recorded Dr. F. W. Edridge-Green's opinion that when the race has become more highly "evolved" that number will be considerably increased. Be this as it may, the time has long gone past since men were content to express their sense of all the hues of nature and art under a dozen or so of names.

The invention of the aniline dyes has added considerably to the shades of colour available for textural purposes, and the artist's colourman, even though he has lost the secrets which imparted an eternal youth to the pictures of Raphael's century, at least can present the modern painter with a range of pigments undreamt of by the great Italian masters. Of the new dyes fashion has been quick to take advantage, and has expended some ingenuity in finding names for the chameleo hues with which, as the seasons change, she decks her votaries. It is hues with which, as the seasons change, she decks her votaries. It is not to be expected that the average masculine mind will accustom itself to such titles as "nattier blue," and it would probably scorn familiarity with "crushed strawberry," "feuille mort" and colour terms of kindred origin, whilst the inconsequence which leads the creative milliner to label a shade of mauve with the name of a popular queen is not only absurd but aggravating. But the need of an accurate colour nomenclature is not limited to the description of frocks and flowers, and medical men must often have wished for a ready method of exactly translating into words some particular tint. Such a chart as we have mentioned might, for instance, be of the utmost service to the descriptive dermatologist. who could convey by its aid an accurate word picture of a given skin lesion to anyone possessing a copy of the chart much more readily than to another. The idea is not entirely new to medicine, as it has been adopted on a limited scale in various devices for the estimation of hæmoglobin, but such special colour charts only represent the shades of red. The chemist may well find the new chart welcome in placing on record such colour reactions as are commonly employed in many branches of his analytical work. When we consider its various utilities we feel that many branches of science owe a debt of gratitude to the Royal Horticultural Society for its energy in seeking to establish a chart of International Colour Reference, the production of which, we may add, is an extraordinary tribute to the perfection of modern printing in colour. The address of the society is Vincent-square, London.

WILLIAM HARVEY'S ASSOCIATIONS WITH BIRMINGHAM. To the Editor of The Lancet.

SIR.—Your readers in the Midlands, who are many, should be interested to know that there is a high probability that the discoverer of the circulation of the blood was on one occasion as near to Birmingham as Aston Hall. For all we know to the contrary, Harvey may have been in the town itself, but it is sufficiently interesting to be assured that as the medical attendant on King Charles I., Harvey must have stayed at Aston Hall on the occasion of the King's visit to Sir Thomas Holte of Aston Hall.

The visit of Charles to his venerable host and most loyal adherent Sir Thomas Holte was in October, 1642, when the Royal army was on the march from Shrewsbury to relieve Banbury Castle, the same month in which was fought the battle of Edgehill. The dates are as follow: Charles slept at Aston Hall on the nights of Oct. 16th and 17th, and fought the battle on Sunday, the 23rd. Now, it is absolutely certain that William Harvey was in close attendance on the King during the whole of that autumn campaign. We have

Harvey's own words to that effect. He wrote: "Whilst in attendance on His Majesty the King during our late troubles and more than civil wars," &c. It is known that Harvey accompanied the King when he left London for Nottingham on August 16th, 1642, and that he was beside the King during the whole of the September, in which month he rode over from Nottingham to Derby to visit his friend Percival Willoughby, who has left a record of their conversation on "uterine honeycomb" (epithelioma). It is also certain that Harvey was present at the batile of Edgehill on Oct. 23rd. The two young Princes, afterwards Charles II. and James II., aged 12 and 10 years respectively, were that day left in his charge, and Aubrey distinctly tells us that as they sat in a ditch on the edge of the hill a "bullet from a great gun" made them "move their station." Harvey is known to have attended to the wounds of the gallant Sir Jervais Scrope. The King was in the battle and Harvey was by his side. Banbury surrendered on the 27th of the month, and on the 29th Charles entered Oxford in triumph. Harvey entered it along with him. Aubrey first met Harvey in Oxford. Harvey remained in Oxford for the best part of the next two years studying problems in development.

Seeing, then, that Harvey was in such close and constant attendance on the King from the middle of August to the end of October, 1642, there is no reason at all for refusing to admit that Harvey was with his Royal Master for the two days and nights which Charles spent at Aston Hall. It is extremely unlikely that so distinguished and indispensable a member of the King's household—one enjoying so intimately as Harrey did the Royal friendship—would be asked to sleep elsewhere than in the house of the King's host. Aston Hall had plenty of accommodation for such a party as the King's retinue in time of If any member of the household was asked to "sleep outside" it would not be the physician-in-ordinary to the King and his personal friend, William Harvey. It may therefore be safely assumed that the immortal discoverer of the circulation of the blood passed two nights in that fine old English mansion so close to us, Aston Hall, then quite a new house, for it had been completed only in 1635. Almost all other houses that he visited, not being new at the time, have perished. The enlightened corporation of the city of Birmingham have preserved Aston Hall, one of "the stately homes of England," from vulgar disfigurement and decay, but they did not probably know that whilst doing this they were preserving, as nearly as possible in its original condition, a building which for at least 48 hours sheltered one of England's greatest sons and the world's greatest discoverers. The very staircases exist which Harvey must have climbed, the same ceilings are there which Harvey must have admired. All such tangible and visible links with the past are interesting, but any existing links with Harvey must be precious to all interested in the history of English I am, Sir, yours faithfully, medicine.

University of Birmingham, Oct. 2nd, 1909.

D. FRASER HARRIS, M.D. Glasg.

DEATH FOLLOWING THE USE OF A "CORN-CURE."

An inquest was held at Shoreham (Sussex) on Oct. 2nd on the body of a retired master mariner, aged 59 years. Of late years he had not enjoyed the best of health and latterly he had been troubled with a soft corn between the middle and fourth toe on the left foot. Without seeking proper advice deceased used a "corn-cure" The trouble increased until medical advice was obtained. Dr. C. R. Wood, who was called in, found a large irritable and inflamed ulcer, while the skin round the base looked as if it had been burnt by some corrosive liquid. The ulcer penetrated into the joint of the toe and inflammation spread to the foot. The toe was amputated, but after the operation the wound showed little tendency to heal, the tendons of the foot became gangrenous, and death supervened. Dr. Wood told the coroner that he had examined the "corn-cure" which the deceased had used, and said it was one of numerous preparations containing salicylic acid which was strongly corrosive, and he thought elderly persons should be warned of its use. The coroner (Mr. F. W. Butler) said it should be brought home to those who had the selling and preparation of these applications that it was most desirable to caution people regarding them. The jury returned a verdict that death was due to acute septicæmia following the application of a corrosive liquid to a soft corn on the foot.

THE WRITINGS OF THE LATE DR. G. M. BEARD.

If any readers of THE LANGET have in their possession, or know of the whereabouts of, any books, pamphlets, manuscripts, or letters written by the late Dr. George Miller Beard, his daughter Miss Grace Alden Beard, of 675, Flabbush Avenue, Brooklyn, New York, would be glad to receive a communication from them. The object of this request is to obtain all possible data preliminary to a republication of some of Dr. Beard's neurological and psychological writings, and to a presentation of certain manuscripts never before printed.

A LONG-LIVED COUNTRYSIDE.

A MEDICAL correspondent has sent us an interesting extract from the Chard and Ilminster News, for the accuracy of which he is able to vouch as he is the professional advisor of all the persons mentioned with the exception of Sarah Morris. He had attended Jacob Trott for some years before his death. The extract is as follows: "Chard has recently lost its oldest resident, Jacob Trott, of Clarke's Row, who was in his 97th year, and could thus remember the battle of Waterloo.

Trott, however, could not claim longest residence in the town, as he was born at Broadway, and had only been in Chard 24 years. He was blind for many years previous to his death. His two sisters, who pre-deceased him, attained the ages of 84 and 80, while a daughter of the old man is in her 73rd year. Trott's remarkable age led us to inquire as to whether there were any other nonogenarians living in the district. Our quest was not in vain, for we find that at Tatworth there is a Sarah Morris, aged 93; in High-street, Chard, Eliza Tucker, 90; at Winsham, Saml. Spurdle, 91; at Purtington, Uriah Samways, 90, who still continues his occupation as a shepherd; and at Bath-lane, Chard, Mary Batten, 90, who is still quite proficient with her needle. The combined ages of these five persons thus aggregate 454 years, which, if not constituting a record, must run very close.'

A CUSTOMS PROBLEM.

OUR Australian correspondent writes that the Victorian Customs officials were recently puzzled under what heading to class an importation of sun-dried lizards which a wealthy Chinese citizen had made for the purpose of using as a drug. The lizards are ground into powder and believed to possess much medicinal virtue. Eventually it was decided that the lizards should be classed "unenumerated" and admitted duty free. The incident calls to mind Mr. Punch's joke of the maiden lady, travelling with a domestic menagerie, and being told by the porter, from whom she has inquired as to the tickets necessary for her pets, that the tortoise was an insect.

A SHEET ALMANAC FOR THE UNIVERSITY OF LONDON.

A SHEET almanac has been instituted for the University of London, and it is proposed to continue the publication annually. The upper half of the almanac consists of a beautiful drawing of the University buildings, executed by Mr. W. Monk, the cost of the drawing having been defrayed by the Chancellor. A certain number of prints of the drawing have been made upon Japanese paper and will be sold apart from the almanac. The price of the almanac will be 2s. 6d., and the special prints will be sold at 5s. Application should be made to the University or to the following booksellers—Messrs. A. and F. Denny, 147, Strand, W.C., and Mr. H. K. Lewis, 136, Gowerstreet, W.C.

W. W. S. (Munich).-Delusions associated with the human excretions are by no means confined to malarial insanities. Such cases as our correspondent describes are familiar to any person acquainted with mental disease. They are perhaps explained to some extent by the loss of the higher cerebral powers of inhibition, which is characteristic

COMMUNICATIONS not noticed in our present issue will receive attention in our next.

Medical Diary for the ensuing Beek.

ROYAL SOCIETY OF MEDICINE, 20, Hanover-square, W.

TUESDAY.

SURGICAL SECTION (Hon. Secretaries—Walter G. Spencer, Jonathan Hutchinson): at 5.30 P.M.

Paper:
Mr. Rickman J. Godlee: Prognosis in some Inflammatory
Diseases of the Lungs and Pleura commonly treated
Surgically.

THURSDAY.

Obstetrical and Gynæcological Section (Hon. Secretaries-William J. Gow, W. Rivers Pollock): at 7.45 p.m.

Presidential Address:
Dr. H. Macnaughton-Jones.

Dr. J. M. Munro Kerr: A Case of Placenta Prævia in which it was deemed advisable to perform Cæsarean Section.
Dr. J. Curtis Webb: Points on the Use of, and Indications for, Electro-therapy in some Gynecological Affections.

FRIDAY.

ELECTRO-THERAPEUTICAL SECTION (Hon. Secretaries—Reginald Morton, G. Harrison Orton): at 8.30 p.m.

Presidential Address:
Dr. Samuel Sloan: Electro-therapeutics in Gynæcology.

N.B.—Fellows of the Society are entitled to attend and to speak at all Meetings.

MEDICAL SOCIETY OF LONDON, 11, Chandos-street, Cavendish-

MONDAY.—8 P.M., General Meeting. 8.30 P.M., In-coming President's Address.—Mr. H. Lett: Two Cases of Perforation of the Small Intestine.

UNITED SERVICES MEDICAL SOCIETY, Royal Army Medical College, Millbank, S.W.

WEDNESDAY.—8.30 P.M., Lieut.-Colonel P. J. Freyer, I.M.S. (R.):
Total Enucleation of the Prostate; Practical Observations on
the Operation.

SOCIETY OF TROPICAL MEDICINE AND HYGIENE, 11, Chandos-

street, Cavendish-square, W.

FRIDAY.—8.30 P.M., Discussion on Recent Advances in our Know-ledge of Sleeping Sickness.

LECTURES, ADDRESSES, DEMONSTRATIONS, &c.

ROYAL COLLEGE OF SURGEONS OF ENGLAND, Lincoln's Inn

FRIDAY.—5 P.M., Prof. Keith: Specimens illustrating Various Forms of Constrictions and Occlusions Found in the Course of the Alimentary Canal. (Museum Demonstration.)

MEDICAL GRADUATES' COLLEGE AND POLYCLINIC, 22,

IEDICAL GRADUATES
Chenies-street, W.C.
Monday.—4 P.M., Dr. S. E. Dore: Clinique (Skin). 5.15 P.M.,
Lecture:—Dr. H. Campbell: Treatment of Neuralgia.
TUESDAY.—4 P.M., Dr. E. Wynter: Clinique (Medical). 5.15 P.M.,
Lecture:—Dr. E. C. Hort: Rational Immunisation from a Practical Standpoint.
Wynter Clinique (Surgical). 5.15 P.M.,
Wynter Clinique (Surgical). 5.15 P.M.,

Practical Standpoint.
WEDNESDAY.—4 P.M., Mr. T. Walker: Clinique (Surgical). 5.15 P.M.,
Lecture:—Dr. G. H. Savage: Moral Insanity.
THURSDAY.—4 P.M., Sir Jonathan Hutchinson: Clinique (Surgical).
5.15 P.M., Lecture:—Mr. L. Mummery: The Diagnosis and
Treatment of the More Serious Forms of Colitis.
FRIDAY.—4 P.M., Mr. W. Stuart-Low: Clinique (Ear, Nose, and
Throat).

POST-GRADUATE COLLEGE, West London Hospital, Hammersmith-

oad, W.

MONDAY.—10 A.M., Lecture:—Surgical Registrar: Demonstration of Cases in Wards. 2 p.m., Medical and Surgical Clinics. X Rays. Mr. Dunn: Diseases of the Eyes. 2.30 p.m., Operations. 5 p.m., Opening Lecture:—Prof. T. Schott: A Renewed Research on the subject of Acute Overstraining of the Heart.

TUESDAY.—10 A.M., Dr. Moullin: Gynrecological Operations. 12.15 p.m., Lecture:—Dr. Pritchard: Practical Medicine. 2 p.m., Medical and Surgical Clinics. X Rays. Dr. Davis: Diseases of the Throat, Nose, and Ear. 2.30 p.m., Operations. Dr. Abraham: Diseases of the Skin. 5 p.m., Lecture:—Dr. R. Jones: Symptomatology of Mental Diseases.

WEDNESDAY.—10 A.M., Dr. Saunders: Diseases of Children. Dr. Davis: Diseases of the Throat, Nose, and Ear. 12.15 p.m., Lecture:—Dr. G. Stewart: Practical Medicine. 2 p.m., Medical and Surgical Clinics. X Rays. Mr. B. Harman: Diseases of the Byes. 2.30 p.m., Operations. Dr. D. Robinson: Diseases of Women. 5 p.m., Lecture:—Dr. R. Morton: X Ray Examination of the Thorax.

Thursday.—10 a.m., Lecture:—Surgical Registrar: Demonstration

THURSDAY.—10 a.M., Lecture:—Surgical Registrar: Demonstration of Cases in Wards. 12 noon, Pathological Demonstration:—Dr. Bernstein. 2 p.M., Medical and Surgical Clinics. X Rays. Mr. Dunn: Diseases of the Eyes. 2.30 p.M., Operations. 5 p.M., Lecture:—Mr. Ll. Williams: Dental and Oral Conditions Influencing the General Health.

ENDAY.—10 a.M. Dr. Moulling. Gypersclopical Operations. 2 p.M.

Influencing the General Realth.

FRIDAY.—10 A.M., Dr. Moullin: Gynacological Operations. 2 P.M.,
Medical and Surgical Clinics. X Rays. Dr. Davis: Diseases of
the Throat, Nose, and Ear. 2.30 P.M., Operations. Dr. Abraham:
Diseases of the Skin. 5 P.M., Lecture:—Mr. Etherington-Smith:

SATURDAY.-10 A.M., Dr. Saunders: Diseases of Children. Harman: Diseases of the Eyes. Dr. Davis: Diseases of the Throat, Nose, and Ear. 12.15 P.M., Lecture:—Dr. G. Stewart: Practical Medicine. 2 P.M., Medical and Surgical Clinics. X Rays. 2.30 P.M., Operations. Dr. D. Robinson: Diseases of Women.

EDITORIAL NOTICES.

It is most important that communications relating to the Editorial business of THE LANCET should be addressed gentleman who may be supposed to be connected with the Editorial staff. It is urgently necessary that attention should be given to this notice.

It is especially requested that early intelligence of local events having a medical interest, or which it is desirable to bring under the notice of the profession, may be sent direct to this office.

Lectures, original articles, and reports should be written on one side of the paper only, AND WHEN ACCOMPANIED BY BLOCKS IT IS REQUESTED THAT THE NAME OF THE AUTHOR, AND IF POSSIBLE OF THE ARTICLE, SHOULD BE WRITTEN ON THE BLOCKS TO FACILITATE IDENTI-FICATION.

Letters, whether intended for insertion or for private informa-tion, must be authenticated by the names and addresses of their writers—not necessarily for publication.

We cannot prescribe or recommend practitioners.

Local papers containing reports or nows paragraphs should be marked and addressed "To the Sub-Editor."

Letters relating to the publication, sale and advertising departments of THE LANCET should be addressed "To the Manager,"

We cannot undertake to return MSS. not used.

MANAGER'S NOTICES. TO SUBSCRIBERS.

WILL Subscribers please note that only those subscriptions which are sent direct to the Proprietors of THE LANCET at their Offices, 423, Strand, London, W.C., are dealt with by them? Subscriptions paid to London or to local newsagents (with none of whom have the Proprietors any connexion whatever) do not reach THE LANCET Offices, and consequently inquiries concerning missing copies, &c., should be sent to the Agent to whom the subscription is paid, and not to THE LANCET Offices.

Subscribers, by sending their subscriptions direct to THE LANCET Offices, will insure regularity in the despatch of their Journals and an earlier delivery than the majority

of Agents are able to effect. THE COLONIAL AND FOREIGN EDITION (printed on thin

paper) is published in time to catch the weekly Friday mails

to all parts of the world. The rates of subscriptions, post free, either from THE LANCET Offices or from Agents, are :-

TO THE COLONIES AND ABBOAD. FOR THE UNITED KINGDOM. One Year 21 12 6 | One Year 21 14 8 | Six Months 0 16 3 | Six Months 0 17 4 | Three Months 0 8 2 | Three Months 0 8 8

Subscriptions (which may commence at any time) are payable in advance. Cheques and Post Office Orders (crossed "London County and Westminster Bank, Covent Garden Branch") should be made payable to the Manager, Mr. CHARLES GOOD, THE LANGET Offices, 423, Strand, London, W.C.

TO COLONIAL AND FOREIGN SUBSCRIBERS.

SUBSORIBERS ABROAD ARE PARTICULARLY REQUESTED TO NOTE THE RATES OF SUBSORIPTIONS GIVEN ABOVE. It has come to the knowledge of the Manager that in some cases higher rates are being charged, on the plea that the heavy weight of THE LANCET necessitates additional postage above the ordinary rate allowed for in the terms of subscriptions. Any demand for increased rates, on this or on any other ground, should be resisted. The Proprietors of THE LANCET have for many years paid, and continue to pay, the whole of the heavy cost of postage on overweight foreign issues; and Agents are authorised to collect, and generally do so collect, from the Proprietors the cost of such extra postage.

The Manager will be pleased to forward copies direct from the Offices to places abroad at the above rates, whatever be the weight of any of the copies so supplied. Address— THE MANAGER, THE LANCET OFFICES, 423, STRAND, LONDON, ENGLAND.

SOLE AGENTS FOR AMERICA-Messrs. WILLIAM WOOD AND Co., 51, Fifth Avenue, New York, U.S.A.

METEOROLOGICAL READINGS.

A Presidential Address

THE RELATION OF MEDICINE TO THE ANCILLARY SCIENCES.

Delivered before the Medical Society of London on Oct. 11th, 1909.

BY SAMUEL WEST, M.D. Oxon., F.R.C.P. Lond., PHYSICIAN TO, AND LECTURER ON MEDICINE AT, ST. BARTHO-

GENTLEMEN,—To be called upon to preside over a society so old and honourable as the Medical Society of London is a distinction I greatly prize. I am proud to think that my name will be inscribed on the walls of the room in the long list of eminent men who have occupied this chair. I trust that I shall be equal to the responsibilities you have placed upon my shoulders and that with your cooperation during my year of office the traditions of the society will be worthily maintained.

It is the custom for the new President to deliver an address before proceeding with the business of the session and I shall follow the custom by expressing a few thoughts which have come into my mind.

I have drawn up a synoptical table which is intended to show the Relation of Medicine to the Ancillary Sciences. Incidentally it represents also the medical curriculum of the present day and upon this aspect of it I will make a few observations before passing to other matters. Such a synopsis shows what a highly specialised product the modern doctor is. After reaching a certain standard of school education the student commences his professional curriculum with chemistry, physics, and general biology. He then begins his more technical work—the biology of man with normal anatomy and physiology. This completes the first part of his professional work. From the normal he passes to morbid anatomy and morbid physiology, which together form the subject of pathology. From the laboratories he now goes to the wards where he is to study the diagnosis, natural history, and prognosis of disease. This done, he should be ready for the study of the means of prevention and cure of disease. What a long and varied training!

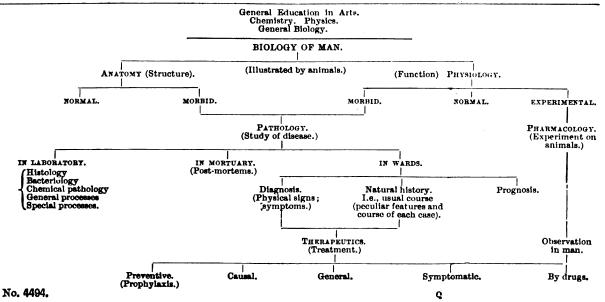

How can all this work be compressed within the five short years of student life? Only it is clear by so arranging and mapping out the time that the student may not waste a moment, for he has not one to spare. His whole time is

to another, as he is directed by his teachers, with hardly time to think, and certainly without leisure to digest and properly assimilate what he has been taught. Even then five years is all too short and many students require longer even for the pass examination.

With such a hurry-scurry, with so much to do and so little time to do it in, the medical teaching of the present day is, and must be, an organised system of cramming. Cramming is not education. It strains the memory and does not stimulate the power of thinking. Real education is a process of growth and development for which time is essential. Any system of education must be bad in principle which does not recognise this fact and which demands more than can be really acquired in the time given. Hurried growth is unsound growth. To cram is not to learn. Stuffing may make Strasburg geese: pâté de foie gras has a commercial value, but a fatty liver is a disease even in a goose. To be always fed with predigested pap injures the vigour of any animal. The medical student of to-day is largely spoon-fed. If he remembered all he had been stuffed with he would be a monstrosity fit only for a museum. If it were not for his natural robustness of body and mind, his general common sense, his hard work, and the splendid powers of forgetting, which he shares with other men, the curriculum would ruin his mental constitution.

After all, the end and aim of all this work is to make the student a practical doctor, an object which too often seems to be lost sight of in the controversies of rival educationalists. So much time is spent in preparing the student to be a doctor that there is little or none left to make him one. In other words, so much time is spent upon preliminaries that the practical clinical work is scamped. The result must be a less finished and complete article than such a curriculum would seem to promise. As an examiner in different licensing bodies now for many years I have come to the conclusion, which I regret but think it my duty to state, that the general standard of clinical knowledge in the final examinations has been steadily and progressively falling. It is only after the student has added to all his preparatory work some clinical experience that the result of all this preparation becomes manifest. If each student could add to his curriculum a year of residence in a hospital as a house officer, without any examination to work for, he would obtain what is lacking. Where the student is so circumstanced that this is possible a good article is produced, better than has been produced hitherto, for there is no doubt that the general standard of efficiency among medical men in practice has risen greatly of recent years. But all cannot have the advantage of hospital experience of this kind, even if they can afford the time and money. Instead of gaining practical experience in spent in rushing from one subject to another, from one place the wards while they are students, when mistakes do no

Synoptical Table, showing the Relation of the Ancillary Sciences to Medicine.

harm and can be corrected, they have to learn it later in practice where mistakes are serious to themselves and to

their patients.

What, then, is the remedy? Obviously to cut down the curriculum until the work required is not more than can be accomplished by the average man in the time allotted to it. Each preliminary subject must be pruned, and all that is not essential ruthlessly cut out. I am glad to think that the most experienced teachers are of this opinion, so that there is some hope of a satisfactory solution being reached at last. The present muddle, for a muddle it is, has largely arisen from the want of that control which medicine should exercise over the whole curriculum, preparatory as well as professional. The object is to make a man a doctor, and the doctors themselves are the best judges of what is necessary for that purpose. At present the teachers in each preliminary subject have been allowed to prescribe what they consider necessary for an elementary knowledge of the subject; each has added a little to the mass until the total burden is too great for any but the strongest shoulders to carry. The burden must be lightened. The work in each part must be strictly defined. This is the use of a syllabus, not so much as a guide to the student, but as an indication to the teacher and a check upon the examiner. The relative value of the different parts of the work must be defined. The perspective of the medical curriculum has been lost. It can only be regained by medicine resuming the control over the whole medical curriculum, preparatory as well as professional. This control it has in theory, but not in practice. The time has now come when in the interests of medicine and of the students that control must be resumed and effectively

My object in drawing out this synoptical table, however, was not to hold a tirade against the present system of medical education. It was quite a different one. I wished to show the position which medicine holds in relation to the ancillary sciences, and which in the face of the aggressive enthusiasm of some of the younger specialties is liable to be lost sight of.

Medicine, as the table shows, consists of Pathology, or the Science of disease, and of Therapeutics, or the Treatment of disease.

Pathology may be studied in the laboratory by the pathologist, so-called, or in the wards by the physician or clinician. Their objects are the same. They each investigate the problems of disease; their difference is not one of subject or of method, but only of place of study. The pathologist has the advantage that he can determine beforehand the investigation he wishes to make, can invent his own experiments, which he can perform at his own time and in his own way—chiefly, of course, upon animals and in his laboratory. The clinician studies morbid man and not animals, cannot select his own experiments, but must take them as they come and when they come, and the clinician's workshop is the ward. Clinical investigation in the wards is as much a science as pathological investigation in the laboratory. The same faculties are required in both pathologist and clinician, the same care and skill in observation, the same scientific use of the reason and imagination to create his theories, and the same judgment in putting his theories to the test. Each is the necessary complement of the other. The theories of the clinician must be taken to the pathological laboratory and worked out there, while the theories of the pathologist, so far as based upon the observations upon animals, cannot be accepted as applying to man till they have been tested and checked in the wards. Medical science is not confined within the walls of the laboratory.

To assume an antagonism, which, if it exists, exists only in the mind and attitude of rival practitioners, and not in the nature of things, can only retard science by exciting jealousy, where there should at the most be nothing more than friendly rivalry. The problems of medicine can no more be worked out in the laboratory alone than they can in the wards alone. It is only by the closest coöperation between the pathologist in his laboratory and the clinician in his wards that the complicated problems of medicine can be solved. Each looks at the subject from a somewhat different point of view and sees it therefore in new lights, and every new aspect of a problem suggests new methods of dealing with its solution.

Clinical medicine and pathology, then, are but two departments of the same science and are the complement the one of the other. For a right understanding of medicine it must

be studied in both places alike, and the clinician is as necessary as the pathologist.

The relation of medicine to normal physiology is equally close. Physiology is the child of medicine, for it was the study of the morbid that showed the necessity of a knowledge of the normal. Now for the convenience of education the study of the normal rightly precedes that of the morbid—so it comes that medicine is sometimes regarded as applied physiology—but it is of course far more than this. Much as medicine receives from physiology, it amply repays the debt it owes by testing and confirming the statements of physiology, and by suggesting and carrying out new lines of research and investigation. I do not propose to refer to the gifts of physiology to medicine, but rather to speak of some of the contributions of clinical medicine to physiology.

I suppose no physiologist would dispute the debt that physiology owes to clinical medicine in the investigation of the functions of the nervous system. The localisation of function in the brain was largely based upon the observations of clinical observers, among whom Hughlings Jackson, a former President of this society, holds the place of honour. Confirmed and extended in the laboratory, the conclusions he drew from observation in the wards form the basis of our present knowledge.

A great deal of our knowledge, too, of the functions of the spinal cord is due to the patient observation of clinical facts and their association with results of post-mortem examination. Though laboratory experiments have done so much to confirm this work, still they are coarse and clumsy compared with those experiments which Nature performs in disease.

Clinical observations led Hughlings Jackson some years ago to a theory of the respiratory mechanism which, though correct as I take it to be, has not yet found its way, I believe, into the physiological text-books. It is this, that in the nervous mechanism of respiration there is a voluntary or cerebral innervation as well as an automatic spinal centre, and that these are to a great extent independent of one another. The clinical facts upon which this theory rests are that in hemiplegia while the automatic or ordinary movements of respiration remain equal on the two sides, or may be possibly even exaggerated on the paralysed side, the voluntary movements of the paralysed side are markedly impaired. 1

The function of the thyroid gland was little understood until the discovery of myxædema as a disease, and its association with the thyroid gland determined. The cure of this condition by the administration of thyroid extract not only showed the importance of the thyroid gland to the body, but threw a new light on the whole question of internal secretion.

The study of Addison's disease, again, has shown one at any rate of the functions of the suprarenal gland, though treatment by suprarenal extract has proved disappointing.

The function of the pituitary body was, and I suppose still is, unknown, but the association of acromegaly with disease of it has given fresh interest to its study.

These are surprising and unexpected associations, and they act as a warning against the assumption that those parts of the body the use of which is not at the time known are of no use at all and form fit material for the surgeon's knife. Who can say that the indiscriminate removal of tonsils, adenoids, and appendices may not produce unexpected and undesirable results? Modern surgery, which makes operation so simple and safe, may bring new and unsuspected dangers with it.

The cachexia which develops in the later stages of granular kidney has a suggestive likeness to the cachexia of Addison's disease and raises the question whether the kidney too may not have an internal secretion. This question is still subjudice. My own clinical experience leads me to the opinion that the kidney has such an internal secretion and that it is to the failure of this that the renal cachexia is due. Although the administration of renal extract often fails in the advanced cases of granular kidney in which it is used, still the failure does not prove that it would not be useful if administered in earlier stages of the disease. I have had some very striking instances of unexpected improvement under its use. The most remarkable occurred in a very long-standing and apparently hopeless case of chronic parenchymatous nephritis. The renal extract, however, must be freshly made, for there is no preparation of it which will keep.

What a stimulus has the clinical significance of glycosuria given the study of carbohydrate metabolism!

In the physiology of the blood the recent additions to our knowledge come almost entirely from clinical sources. malaria and kindred affections we seem now to be wandering in a wonderland where the waving of the fairy wand of science banishes the demon of disease and converts a charnelhouse into a paradise.

A new field of physiological research has been opened out in respect of the heart by the recent study of the bundle of His and the clinical observations upon the phenomena included under the term "heart-block."

But even among the common things of the heart there are some which, clinical observation suggests, require reconsideration.

To take, for example, the sounds of the heart. We are taught that the second sound of the heart is due to the closure of the aortic and pulmonary valves, and that the second sound at the apex is merely the second sound at the base transmitted to the apex. If this were the whole truth there ought to be a definite and constant relation between the intensity of the second sound at the base and that at the apex. But clinical observation shows that this is not the case, for the second sound may be loud at the base and absent at the apex or be heard loudly at the apex and be feeble or even absent at the base, so that there is no constant relation between them. In mitral stenosis the second sound is often completely absent at the apex and yet audible distinctly at the aortic base and loudly accentuated at the pulmonary base. Clinical observation thus leads to the conclusion that the cause of the second sound is not the same at the apex as at the base. Inasmuch as the chief effect of mitral stenosis is to prevent the blood passing readily into the ventricle from the auricle, so that it can only trickle through instead of running, as it does in a healthy heart, in a free and unimpeded stream, we may suppose that it is the impact of the blood upon the wall of the ventricle as it passes from the distended auricle at the commencement of the ventricular diastole which produces the second sound at the apex in health. Whether this explanation be satisfactory or not it is the only one I can think of. Some explanation is required, and the question is obviously of great physiological importance.

The length or duration of the heart sounds is another question of importance in clinical medicine, for upon it depends a right understanding of cardiac murmurs. The second sound is short but the first is long. To hear the heart-sounds as clearly as we do there must obviously be distinct intervals of some duration between them. These intervals may be occupied by an abnormal noise which is called a murmur. Yet murmurs are often described as replacing the heart sounds. In the case of the second sound diastolic murmurs always do more than this, for they last much longer, even it may be throughout the whole diastolic period. The question, then, of the length of the heart sounds is only of real importance in relation to the first sound. The difference of teaching is shown by the different diagrams given of the first sound. It is often represented as if extending through the whole of the systolic period, yet clinical observation shows that it does not really extend more than half way, for there are many cases at the bedside in which the sounds appear perfectly normal to the ear and yet there is in addition a systolic murmur equal in duration to that of the first sound. If the first sound lasted through the whole of systole no definite distinction could be drawn between an altered heart-sound and a murmur, as must be done if a correct diagnosis of cardiac lesions is to be made. This difference of opinion will, I suppose, continue till some means is found by which the heart sounds can be measured and made to record graphically their own duration. The only observations I know which bear on this point are those of Einthoven and Geluk.² Their results support my views.

Another piece of physiological teaching which I cannot reconcile with clinical observation is that of the sphincter action of the cardiac muscle at the mitral and tricuspid orifices. According to this theory the mitral and tricuspid valves are not competent to close the orifice unless they be first contracted by the sphincter action of the heart muscle. A priori it would seem incredible that so important an organ as the heart should have such a narrow margin of reserve that mere muscular weakness should render the pump ineffective. A priori reasoning is risky. In my mind the question is settled by the following considerations: (1) That In my mind the

if the valves were incompetent a regurgitant murmur would be the result; (2) that with organic disease which leads to regurgitation the murmurs are propagated in definite directions; and (3) that the murmurs are not so propagated in the great majority of cases when they are associated with simple cardiac weakness. If the murmurs constantly vary in so marked a way the cause of them can hardly be the same. So this sphincter-action requires reconsideration and the experiments upon which the theory rests call for repetition.

The last question I would raise in connexion with the heart is the problem of its nutrition. We are taught that this depends upon the coronary arteries alone. We were once told that the coronary arteries did not anastomose and that each was independent. But as I showed many years ago, the anastomosis is extremely free and nothing is easier with proper care than to inject nearly the whole heart from either

The question I would now raise is whether in fact the coronary arteries are indeed the only source of blood-supply to the heart. My doubts rest upon the fact that the mouths of the coronary arteries are often greatly constricted by atheroma without the heart suffering much in power. I have even seen the mouth of one coronary artery completely obliterated and the other so small that the finest probe could only be introduced with difficulty into it. It was quite impossible that the blood-supply of that heart could have been obtained through those obliterated coronary arteries at all. It is difficult to see what other source of supply there can be in such cases unless there be vasa propria cordis opening directly from the cavities of the heart itself.

I mention these points in connexion with the heart as examples of subjects of research suggested simply by clinical observation. I do not propose to pursue this subject further, but I think it will be accepted that there is no organ in the body upon the pure physiology of which clinical observation cannot throw, even if it has not already thrown, much light. So that clinical medicine is the partner, and no sleeping partner either, of pure physiology as it is of pathology.

I turn now to pharmacology and its relation to medicine. Pharmacology is a special branch of experimental physiology and deals with the physiological action of drugs or remedies. Many of the remedies selected for investigation are those which have been found of use at the bedside. Many new remedies have come from the pharmacological laboratory to the wards, and their number is rapidly increasing under the stimulus of the theory that chemical constitution is a guide to physiological action. The action of remedies upon healthy animals in the laboratory is no proof that they will have similar action upon sick men. The results of pharmacological experiments must therefore be tested in the wards before they can be accepted for use in medicine.

To call treatment based on laboratory experiment rational and scientific and that based on bedside experience empirical implies a difference which does not exist, and would seem to suggest that clinical observation is neither rational nor scientific. Yet the same care and skill in observation are required in either case and the difficulties to be surmounted are much greater in the wards than they are in the laboratory. According to this view, if a remedy were found to do good in the treatment of disease its use would be rational if a physiological explanation could be given, and it would remain under the stigma of empiricism if no physiclogical reason could be given, even if, as has sometimes happened, the physiological reason assigned has proved ultimately to be wrong. Yet whether the physiological explanation of its action can be given or not, it would seem to be the height of unreason to refuse to use a remedy of proved clinical value because its action could not be explained.

So, again, the treatment of symptoms is often disparaged as essentially unscientific, yet surely if you cannot cure the disease but can relieve its symptoms it would be irrational not to do so, though the reason of the relief given were not known. Symptoms are disorders of function produced by A particular symptom, for example, might be due to the action of some chemical substance produced by the disease, and if this substance could be neutralised or decomposed the symptom would disappear. If it could be shown that this was actually what occurred, the discovery would be

^{*} Archiv für Gesammte Physiologie, 1904, vol. lvii., p. 607.

regarded as of the highest scientific value. A fact is a fact whether it can be explained or not, and there are many such facts in symptomatic treatment. That the explanation is not forthcoming is not due to the want of science in the clinical observer, who is busy collecting such facts, but to the backward condition of physiological knowledge. The terms "rational" and "empirical" should therefore be dropped as suggesting undue assumption and unworthy disparagement.

In pharmacology as in physiology the work in the wards is the necessary complement of the laboratory. The clinician may suggest problems for the pharmacologist to tackle, the pharmacologist may supply new remedies for the clinician to try—loyal cooperation on equal terms between each is

necessary for the progress of science.

Recently the bacteriologist has entered the domain of therapeutics with antitoxic sera and vaccines. Prepared as these remedies must be in special laboratories, it is only in the wards that their true value can be determined. The results are sometimes striking, but often, alas, the promises of the laboratory fail to be realised in the wards. On this subject I would raise a question—Whether the prolonged administration of these remedies over weeks and months may not produce serious effects upon the general health. I have myself observed a few cases in which a profound cachexia developed from which the patient died. The result was attributed to the disease and perhaps rightly. Yet I could not help feeling some doubt whether it was not, in part at least, the result of the prolonged use of the remedy. I have made inquiries of some practitioners of experience and find that there is an impression among them also that it may be so. I know that it is stated that these remedies do no harm and may be used indefinitely with advantage. It would be strange if remedies so powerful for good were incapable of doing harm. At any rate, the question deserves consideration.

The conclusion of the matter seems to be that it would be unwise to let the enthusiastic physiologist, bacteriologist, or pharmacologist run loose in the wards without the advice and controlling influence of the clinician, and that it would

be risky both to science and to the patient.

The proper position of each of the ancillary sciences is side by side with medicine. They must all work loyally together in a common search after truth. But if one must be pre-eminent it is surely medicine, which has the right to pre-eminence as the parent of them all. To speak of the clinician or physician as obsolete, effete, or an anachronism, is midsummer madness. The clinician is as necessary to the progress of medical science in the present day as the bacteriologist, physiologist, or pharmacologist. Indeed, there never was a time, I believe, when the mature experience and cool judgment of the practised clinician was more necessary than now, to put brilliant but crude theories to the test, and in general to counteract the separatist tendencies of modern specialism.

INCORPORATED INSTITUTE OF HYGIENE.—A COURSE of popular lectures (with practical demonstrations) on food and dietetics, cooking, home hygiene, and home nursing will be delivered in the lecture hall of the Institute of Hygiene, 34, Devonshire-street, Harley-street, W., during the coming nine months. They will comprise the following subjects: Food and Dietetics, by Dr. G. Norman Meachen, commencing on Oct. 5th; Cooking (with practical demonstrations), by Mrs. C. L. Wilson, L.L.A., commencing on Oct. 12th; Home Hygiene, by Dr. Lilian M. Chesney, commencing on Oct. 19th; and Home Nursing (with practical demonstrations), by Miss Isabel Macdonald, commencing on Oct. 26th

Tuberculosis in the Black Country.—The South Staffordshire Joint Small-Pox Hospital Board is considering a scheme for the utilisation of its small-pox hospital as a sanatorium. During the four years the hospital has existed no patient has been treated there. In the board's area there are about 1000 consumptives, with 300 deaths annually. Dr. G. Reid and Dr. W. McE. Clendinnen showed by their estimates that by charging 30s. per patient per week the board would effect a saving of £244 annually from the point of view of small-pox hospital maintenance. One-third of the cost would be provided by the board and two-thirds by those who made use of the institution as a sanatorium. A committee has been appointed to consider the scheme.

Introductory Address

Delivered at the Opening of the Winter Session at the University of Liverpool School of Medicine on Oct. 5th, 1909,

By CHARLES A. BALLANCE, M.V.O., M.S. LOND., F.R.C.S. Eng., SUBGEON TO ST. THOMAS'S HOSPITAL, ETC.

LADIES AND GENTLEMEN,—I esteem it a high privilege to have been invited by the Medical Faculty of the young but already famous University of Liverpool to give the introductory address at the opening of this session. Our island country owes much to the enterprise, the energy, and the courage of the inhabitants of this city. No one of us can sail the estuary of the river Mersey without a feeling of legitimate pride.

"That stream which fretted by a thousand prows, No rest, no liquid slumber knows, Whate'er the hour, whatever winds prevail, Behold the outward and the homeward sail."

And stealing silently into our minds, for as a race we tend to conceal our thoughts, come the words civis Britannious sum. To the ignorant it might appear that

"Your mind is tossing on the ocean,"

and that you employ your leisure

"Plucking the grass, to know where sits the wind,"

"For there is a magnet-like attraction in These waters, to th' imaginative power, That links the viewless with the visible, And pictures things unseen. To realms beyond The highway of the world my fancy flies, When, by her tall and triple mast, we know Some noble voyager, that has to woo The trade winds, and to stem th' ecliptic surge."

Though this city is famed for its shipping and its commerce, it is also famous by reason of the literary and intellectual eminence attained by many of its citizens. I will mention only three of them: Mr. Gladstone, Mrs. Hemans, and Ian Maclaren. This is not the proper occasion to speak of Mr. Gladstone's amazing intellect, his illustrious career, and the influence of his personality on the higher ideals of life and conduct; but there is one thing about Mr. Gladstone which, whatever our political views may be, must appeal to the heart of every Briton. He devoted the whole of his life, all the eminent qualities of his mind, and all his physical strength to the rough island story of the land in which we live and which we so much love. The next name is that of Mrs. Hemans. Who, as a child, has not felt a tingling of the blood when reciting the poem descriptive of the steadfastness and heroism of the young boy Casabianca? Who has not been moved by the melody and sweetness of the lines of "The Better Land"? Who of us can now read "The Homes of England" without some feeling of uneasiness and alarm?

"By a divine instinct men's minds mistrust
Rusuing dangers, as by proof we see
The waters swell before a boisterous storm,"

All forbodes peace, yet we live, as a great imperial orator recently said, in an age in which the nations of Europe are engaged in silent warfare, hardly less exhausting and dangerous than open war. This "tacens bellum" may pass at any moment by sudden attack into a struggle for our very existence. England may say with the Psalmist, "I labour for peace, but when I speak unto them thereof, they make them ready to battle." Has not the time come "that some personal duty and responsibility for national defence rests on every man and citizen?"

"The stately homes of England,
How beautiful they stand,
Amidst their tall ancestral trees,
O'er all the pleasant land!

The cottage homes of England!
By thousands on her plains,
They are smiling o'er the silvery brooks,
And round the hamlet fanes.
Through glowing orchards forth they peep,
Each from its nook of leaves;
And fearless there the lowly sleep,
As the bird beneath their eaves.

Breathes there the man, with soul so dead, Who never to himself has said, This is my own, my native land!

Oh! where's the coward that would not dare To fight for such a land."

I may detach a passage from Ruskin's lecture on War and y that national defence in Britain at the present time may fitly be described in the words, "Brave men fighting and her cowards thinking." Truly the thoughts of England need good captains' leading now, if ever! Unless Britain awakes from her long sleep, "Ashes to ashes" may be her epitaph, and the beautiful verses of Mrs. Hemans may remain as but a memory of the past, lost beyond recall:-

"When the lamp is shattered,
The light in the dust lies dead;
When the cloud is scattered,
The rainbow's glory is shed."

No, it shall not be-

"Nought shall make us rue, So England to herself do rest but true.

The free fair homes of England! The free fair homes of Bigland!
Long, long in hut and hall,
May hearts of native proof be reared
To guard each hallowed wall!
And green for ever be the groves,
And bright the flowery sod,
Where first the child's glad spirit loves,
Its country and its God!"

The "Name of England," the title of another poem by Mrs. Hemans

A thousand ancient mountains Its pealing note has stirred, Sound on, and on, for evermore, O thou victorious word!

England! what thou wert, thou art! Gird thee with thine ancient might, Forth! and God defend the Right!"

This University had its origin in the wisdom, the forethought, and the enterprise of the citizens of this city. The work already done in it gives assurance of the greatness of its future. A University does not consist alone of the stone and the bricks and mortar of which its laboratories and lecture rooms are constructed, important as these, in a sense, When I was in America I was introduced to Mr. Roosevelt. I opened the conversation by expressing my admiration of the new marble buildings of the Harvard University at Boston on which 5,000,000 dollars had been expended. He replied: "Yes, they are very fine, but, in the case of Universities in general, how much better it would be to spend the money, not first on buildings, but first in the endeavour to induce the wisest and greatest men of the world in the various branches of knowledge to come and fill the professorial chairs."

The real vitalising and energising element, the germinal plasm of the University, is its band of living workers. The individual members of the University pass away, but the body-corporate is endowed with continuous life, but with a life of ever-changing form. This organic body grows from year to year in strength and in knowledge. The knowledge gained by the toil of one generation soon becomes the commonplace of the next. The world moves on in a succession of dreams and their fulfilment, and the wild imaginings of one age become the splendid realities of the next.

"Yet all experience is an arch where thro'
Gleams that untravell'd world, whose margin fades
For ever and for ever when I move."

There is no halt in the beneficent activity of the living workers of the University to increase the sum of human knowledge, and in the medical faculty no rest in the effort to relieve human suffering and to cure disease. The tide in the progression of nature moves with undeviating purpose from incompleteness to completeness, from imperfection to perfection. The further evolution must go on. The succession cannot break. The day of greater knowledge will arrive when the then living workers of your medical faculty willibe able perfectly to control those dread diseases which still confront and baffle us.

The extraordinary evolution and advance of physiology, pathology, medicine, and surgery, since the time when I became a student can only be dimly realised by those who have but lately joined the profession. When I entered the profession the obstacles to the study of human anatomy had been removed, and clinical observation combined with postmortem study had greatly increased our knowledge of disease. The work of the experimental school of Pasteur and Lister had but commenced to influence practice. The surgeons made a point of operating in the oldest of coats bespattered system mainly rests. Without these experimental researches with blood and pus from many a field-day. Intestinal and

gastro-intestinal anastomosis were unknown. The reduction of intussusception was attempted by means of the kitchen bellows. The operations for brain tumour and brain abscess were unknown. No operations were performed on the heart and spleen. Patients with renal or biliary calculi, and with appendicitis or peritonitis, were left to their fate.

Much of what is now current surgical practice was when I was a student considered too hazardous to attempt or was altogether unknown. In one well-known text-book the opinion was expressed that the limit of the surgeon's art had been reached. You, on the other hand, who are about to enter the profession will have unfolded to your view quite another picture. You will find ready to hand a precise and well-proved surgical technique, beautiful aseptic operation rooms, well-equipped laboratories for research, instruments of precision, and elaborate laboratory methods of diagnosis and treatment. You will see an endless succession of major and minor operations, which concern every part and every organ of the human body, being performed successfully day by day. You will witness, and I hope will soon take part in, a constant struggle to improve our operation methods, and a continuous effort by the aid of experiment to attain "things unattempted yet" in surgical practice. Sepsis, diphtheria, typhoid fever, yellow fever, carcinoma following x ray dermatitis, and other diseases take their toll among the heroic workers who are pushing forward in the front rank of the advance of medicine and surgery. The greatest responsibility is demanded of our profession and the highest death-Yet you will find the great doctors of the past, of this age, and of all the coming years "endued with comprehension and a steadfast will to look one step forwards and to secure that step. Adventuring for man's sake, apart from all reward, they seem to long at once to save mankind, to make some unexampled sacrifice in their behalf, to wring some wondrous good from heaven or earth for them, or perish, winning eternal weal in the act."

In pathology and medicine the progress too has been equally extraordinary and remarkable, especially in our knowledge of the intimate pathology of the infectious diseases and of natural and acquired immunity. To me it is an historical fact that I joined in 1884 the first class in bacteriology ever formed in the ancient University of Leipsic. During my medical life the organisms of anthrax, erysipelas, pneumonia, puerperal fever, tubercle, Malta fever, syphilis, cholera, tetanus, small-pox, diphtheria, acute rheumatism, and plague have been identified; and the successful attainment of immunity against diphtheria, typhoid fever, snake venom, rabies and other toxic poisons stands in the front rank of the greatest triumphs of the art of healing. fascinating story of the fight against tropical diseases in which the Liverpool School has played so splendid a part I

have only time to mention. The growth of physiological knowledge is almost past elief. The physiology of the present day has passed beyond the histology and elementary lessons in the functions of organs which I was taught into the higher regions of chemistry and physics. Let me take one example. I doubt whether in 1880 there were half a dozen men in England who really believed in the great doctrine of the localisation of the functions of the brain. In the Physiological Section of the International Medical Congress held in London in 1881 there was a Homeric contest, of transcendent moment to the advancement of knowledge and vital to the interests of mankind, over the dog shown by Professor Goltz and the two monkeys exhibited by Professor Ferrier. Experimental injuries had been inflicted on the cerebral cortex of each of these animals. The condition of the dog was supposed to prove that localisation of function in the cortex cerebri did not exist. One of the monkeys was typically hemiplegic, having lost power in the arm and leg. Professor Charcot remarked as the monkey came into the room, "It is a patient." The other monkey showed no signs of hearing when a percussion cap was snapped in its immediate vicinity; indeed, it was the only animal in the room that did not jump when the explosion occurred. From that day to this, experimental work on the functions of the brain has been in progress. This field of science has been brilliantly illuminated by the epoch-making researches of Professor Sherrington. It is upon his work, and that of many other scientific labourers,

to undertake, as he may with confidence and success at the present time, the removal of many of the gross diseases to which the brain and spinal cord are liable. So far-reaching is the influence of experiment on the progress of treatment that no one of us can separate himself and say physiological experiment has nothing to do with me. Till the functions of the living organs in health are clearly understood, it is not possible for us clearly to understand the changes that occur in the living organs in disease.

The world's most bitter enemies are, as Kipling has finely said, those who would limit and hamper research. It is well for us to remember that the men who are engaged in researches designed to unravel the tangled skeins of truth in the sciences of physiology, pathology, therapeutics, and surgery are following in the footsteps of Pasteur, of Lister, and of all those who have contributed most to the advancement of medical science and the relief of man's suffering.

That great Victorian, the late Sir Theodore Martin, recently expressing his views on the signs of the times asked, Where are the giants? Where are the Palmerstons, the Disraelis, the Gladstones in politics? Where are the giants in literature? Where in any walk of life are Alpine altitudes to be found? As far as our own profession is concerned there is no difficulty in answering this question. The pageant of medicine and surgery of the past 30 years has been the most glorious of all time. The names of Virchow, Helmholtz, Pasteur, Lister, Paget, Metchnikoff, and Foster, would shed a glory upon any age. The progress of medicine in the present day rests in great part on the labours of past generations. As Carlyle so well said: "The craftsmen there, the smith with that metal of his, with these tools, with these cunning methods, how little of all he does is properly his work. All past inventive men work there with him as indeed with all of us in all things. During the American Civil War one of the most famous songs of the soldiers of the North was "John Brown's body is mouldering in the dust, but his soul is marching on.

You, students of medicine of Liverpool, will perhaps have been wondering why I have chosen, briefly and all too inadequately, to sketch the glorious story of the conflict waged and the splendid victories won in recent years by the profession. My object is to stimulate your ambition, to fire your energies and to clench your resolves, to take a manly and noble part in this struggle. Soon those who are prominent now in the fight will have passed away; and in you, if you resolve earnestly to use these early days of your studentship, if you vow your life to medicine, and if you give it to her wholly, "a bright, stainless, perfect life—a knightly life," John Brown's soul will be marching on, and the years of your life will be as full of blessing to humanity

as those of your teachers have been before you.

The life of the student of medicine falls naturally into three periods: (1) The time spent before he registers as a student; (2) the days of his so-called studentship; and (3) the life that dates from the day that he obtains a licence to practise. In all the learned professions such distinctions are more or less artificial. They are entirely artificial in the profession of medicine; for all who enter our profession become students for life. The licence to practise, though it does not close your studentship, does add to your responsibility as you are then commissioned to go forth alone to investigate the phenomena of nature in health and disease. The joy may soon be yours which attends the first realisation of the power of knowledge, the first successful effort to combat some pain or sickness in the body of a patient committed to your charge.

I cannot influence the first period of your lives, but I may express the hope that many of you have taken a degree in Arts before launching yourselves on a voyage destined to lead you far in many of the natural sciences. The more your intellect has been exercised in the classics, in mathematics, in philosophy, and in history, the more easily will you assimilate and delight in the facts, the laws, and the problems of those sciences to which your studies will now be mainly directed. During the strenuous years that are before you, and in the bustle and hurry of the new life you can, if you will, return to the old learning, which may be to you a grand source of relaxation and a perennial pleasure. Our profession demands, not a minimum of general knowledge but the maximum that can be obtained. In my experience the men in our profession who have had the advantage of general culture are, as a rule, abler physicians than can be cast into the scale of life. I fervently wish each of

those who have not, while those who have had only a scientific education seem sometimes to have one side only of their minds developed. If you have not already had this general education you may with industry and perseverance make up the loss, wholly or in great measure, by taking every opportunity of increasing your knowledge of literature, art, and music. Give a definite amount of your time to the study of modern languages, especially French and German, in which languages much of what is best in the medical sciences is now written. Go abroad whenever you can, widen your views of life, learn as I did in a German university laboratory the pleasure of work for the work's sake, appreciate that in science there are no national boundaries, and that not only in Liverpool and in Britain, but in every country, the great, the noble, the unselfish worker in science is to be found.

If you will pardon a reference to my own early days (and a personal note sometimes appeals to an audience more than anything else), I may tell you that I acquired an elementary acquaintance with the Latin and Greek authors, and imbibed a taste for the reading of the Bible, Bacon, Milton, Shakespeare, Spenser, Gibbon, Macaulay, Carlyle, Scott, Dickens, Tennyson, and some other English classics. The study of these alone constitutes a liberal education. I recommend you to have always at hand some volume of English literature which will be to you, as it has been to me, an ever-present source of edification and delight. I am sure it is best not to become so engrossed in the study of the medical sciences as to be insusceptible to the charm and claims of other byways of knowledge. Your life will be spent in the laboratory of the world, amongst diverse types of mankind, and to be in the best sense a successful doctor you must be not only scientific but human.

One word as to exercise. What we want in our schools and in our national life is some middle course between the German method of no play and the English one of all play. Games and amusements occupy too prominent a place in English life. I see nothing but the obligation and privilege of personal service for national defence that will wean our people, high and low, from their present condition of indiscipline, lazy indolence in amusement, and the vice of betting on every game, to the noble virtues of self-respect, unselfishness, and self-sacrifice. "Hustle, bustle, and noise-the jingling of the guinea, the thousand and one meretricious allurements of the age—have for a time dimmed the fair mirror of English life." As Baruch wrote in Babylon, so we may say in some measure of England of to-day: "The young men have seen light and dwelt upon the earth, but the way of discipline (discipline, discipline or knowledge) have they not known, nor understood the paths thereof, nor laid hold of it; their children were far off from that way." A short time ago my car was stopped in the early evening in a suburb of London by a large crowd which collected round a building and which had blocked the whole road. I asked a policeman what was the matter. He said that the crowd consisted of the unemployed waiting to go into a musichall. Again, it is well known that the same class can always find money to go in their thousands, not to a rifle range, but to witness a football match in some distant city.

Before sending my son to a preparatory school I visited some of the best in England, and usually the headmaster early let me into the great secret that all the assistant masters had won their blue at Oxford or Cambridge. I know of one man who telegraphed to his father from the University, "Shall I play for the University or work for my examination?" The father being an Englishman replied, "Play for the University." The son made over a century for his University, and before the match was over he received by telegram an offer of a post, not, as you will probably guess, in an English school, but as steward of a property in his own county. The father on this occasion made a wise choice, for his son had been so intoxicated by the game's madness that the elementary knowledge required for a pass B.A. was beyond his powers. Surely it ought not to be impossible to combine a little learning with cricket; to do otherwise, I would say, is not cricket, but wilful sloth and indolence. Fortunately, that man had not to turn his mind to the study of medicine, for when all is permitted to depend on the skill of one, think on the responsibility of wilful ignorance when the beam of life and death is so nearly balanced that it turns this way or that according to the more or less skill that you a century at cricket for Liverpool, but the pleasure of work done and duty fulfilled is a far greater and nebler end to strive for.

I know of another man, formerly an undergraduate at Oxford, who wrote to his father that if he remained at the University he must row for his college, and that the time spent in training would jeopardise his chance of success at the Indian Civil Service examination. The father replied, "Act as you think is right." The son made the great sacrifice. He left the University and by winning a place at the Indian Civil Service examination secured the reward of true courage.

true courage.

"Judge not what is best
By pleasure, though to Nature seeming meet,
Created, as thou art, to nobler end."

Recogning (and I recogning)

Propose this test, says Browning (and I remember my colleague, the late Dr. Cullingworth, on one occasion quoted these lines):—

"The body at its best

How far can that project thy soul on its lone way."

The second stage of your life lasts from the time you sign on to the day when you receive your diploma. I do not know the causes which have determined your choice of a profession, but let me offer you a most hearty welcome. The study of medicine and the allied sciences confers on you the prospect of the exercise of all the highest and noblest qualities that man possesses; and opens out to you a vision of truth, order, and beauty, ever growing wider and wider as you learn more and more of Nature and her laws. Can any fairer landscape unfold before the gaze of any human being at the outset of his career? It is for you to seize upon Fortune. It is for you to determine the issue. It is true that "Fortune brings in some boats that are not steer'd." but as a rule "Things bad begun make strong themselves by ill." At first your time will be spent in the study of the sciences of chemistry, biology, physiology, and anatomy. Do not simply learn enough to pass an examination. While you are studying anatomy determine to become an anatomist, and so also with each science which claims your attention. It is remarkable how the knowledge gained in the first years of your student life will be of service to you in later years. Bacon and other great thinkers are unanimous in this "that no natural phenomenon can be adequately studied by itself." The natural sciences are so intimately related that each one, in so far as it has been mastered, will illuminate phases and dark areas in the others. If you make good use of the first two years I can promise you that you have laid a foundation which will bear good fruit. Do not be discouraged at the vastness of our art or the narrowness of human wit. Steady, daily industry will soon give you the sweet sense of overcoming. Labour is a moral obligation laid on all men:-

"And does the road lead uphill all the way?
Yes, to the very end.
And will the journey last the whole long day?
From morn till night, my friend."

"Genius," says Carlyle, "means transcendent capacity for taking trouble first of all." There is no palm of victory where there is no struggle. The Hill Difficulty may be climbed by cultivating the habit of industry and Bacon's heaven on earth may be enjoyed by the student of medicine "whose mind moves in charity, rests in Providence, and turns upon the poles of truth." It is equally a moral obligation to cultivate our faculties, as it is customary to exercise our muscles to keep them in order. The keeping of your bodies strong in no wise involves the keeping of your minds weak. Hard work is necessary for any degree of success. It is of paramount necessity that the student should learn something every day—"Now he weighs time, even to the utmost grain." "Having then resolved that you will not waste recklessly but earnestly use these early days of yours, remember that all the duties of her children to Medicine may be summed up in two words-industry and honour. I say first industry, for it is in this that student youth are especially tempted to fail. Secondly, honour. Though it is not exacted of you, yet exact it of yourselves, this vow of stainless truth. Vow yourselves crusaders to redeem that sacred sepulchre. Bind it like a shield about your necks; write it on the tables of your hearts."

When you have finished your preliminary studies in anatomy and physiology the vista of the life before you will become more and more entrancing. The wilderness of truth in the science of medicine, of surgery, and of pathology is no longer pathless. Many of the evergreen glades in bright with promise.

these subjects have been trodden by your predecessors; and your first task is to master the geography of these before contemplating a tour of discovery in new and unexplored fields. As you spend your time in the wards and out-patient rooms bear in mind the lesson taught by Sir George Humphry to generations of Cambridge men—"Eyes first and much, fingers next and less, tongue last and least." Eye diagnosis is of the first importance. It promotes keenness of observation and accuracy of judgment. The cases you have charge of while holding the appointment of clerk and dresser form a standard or guide which will be of service to you all your life. They will not leave your memory if diligently watched and carefully described. Disease recurs, and so in practice you will see similar cases, and your first clinical experience will then be an aid to you in diagnosis, prognosis, and treatment. It is an excellent practice to keep brief private notes of your ward cases. And if you are skilled with the pencil, and the subject lends itself to illustration, make a drawing, which is often better than the most laboured description. If you cannot draw you can at any rate photograph. In a few years by sketching or photography you may accumulate a valuable album illustrative of disease and its treatment.

Nowadays there is much too much tendency to depend on coaching classes—a kind of spoon diet which cuts the ground from under that self-reliance in work and in preparation for examinations from which the best results flow. You cannot become a good doctor without self-sacrifice and persistent personal effort—

"The sweat of industry would dry and die But for the end it works to."

Spoon diet is not fitted for those who wish to attain real knowledge in the natural sciences. Reflection is required, but in the rush and scurry of the present age no time is allotted for this most necessary process. Nothing is more certain than that you cannot gain a reasonable and soul-sufficing knowledge of our art and science by cramming. Time is required. Look into Nature with her vast powers and inexhaustible resources, these are never used for production by sudden and spasmodic efforts. "Consider the lilies of the field how they grow." How, then, can any one of us hope to gain the wisdom and knowledge required for the fight with death except by slow and persevering industry?

There is a point which I must not omit to urge upon you. Never hurt a patient's feelings either of mind or body by unwisely arranged questions or by unnecessary exposure of the person. Ask, for example, if a woman is married before asking whether she has any children, and never inflict pain by rough manipulations in your examination of a case. I well remember the castigation given to a student by the late Dr. Charles Murchison for using unnecessary vigour in percussing out the area of dulness in a case of pericarditis.

It is a common practice to attribute want of knowledge in a class or at an examination to nervousness. In most cases this is an error. Nervousness results, as a rule, from lack of intentness in work, such as dawdling in the wards; and connotes, as a rule, some lack of preparation, some imperfection in personal effort. Do not, then, let any occasion arise in which you may be tempted to make the excuse of nervousness.

A striking example of the importance of attention as a principal factor in the intelligence of animals is related by Dr. Bastian. The facts were communicated to Darwin by the late Mr. Bartlett of the Zoological Gardens. A man who trained monkeys to act, used to purchase common kinds from the Zoological Society at the cost of £5 each, but he offered to give double that price if he might keep three or four of them for a few days, in order to select one. When asked how he could possibly so soon learn whether a particular monkey would turn out a good actor he answered that all depended on their power of attention. If when he was talking or explaining anything to a monkey its attention was easily distracted, as by a fly on the wall or other trifling object, the case was hopeless. On the other hand, a monkey which carefully attended to him could always be trained. So it is with you and with me, and, indeed, all students of medicine, nearly everything depends on the power of attention, for without it knowledge cannot be garnered and the case is hopeless. Those, on the other hand, who cultivate carefully the power of attention have the assurance, not only of present success, but of a future

And now let me say one word to those who may fail in the struggle for prizes, for appointments, and in examinations.

"What though the field be lost? All is not lost—the unconquerable will, And courage never to submit or yield,"

will enable you to make good the failure and redeem the loss. Never say fail—banish such a word, such an idea from your life. I failed in a botany examination a long time ago. am sure it was my own fault. But if you have worked well, as some do who fail, never mind the failure. The work you have already done will bear fruit and promote your success on a future occasion. No good work was ever wholly lost. It is good work which ultimately tells in life and not immediate and maybe transitory success. Your character is in the crucible. Gold must be tried by fire. Immediate success is of less importance than the formation of character. The stay of man in the midst of depression, discouragement, and defeat is the consciousness that he has faithfully rendered obedience to the command of the Preacher: "Whatsoever thy hand findeth to do, do it with thy

The third period of your life begins when you receive your diploma. It remains for me to say a few words on the life of the doctor. You will soon find that you have no hours of work or rest that anybody is bound to respect. You have no evenings, no nights, and no Sundays which you can call your own. A friend of mine living in a country town and having a practice extending 15 miles in every direction around it, received on a certain Saturday evening five letters from as many clergymen asking him to call immediately after morning service on the following day—requests which required a drive of 40 miles: and showed a thoughtful interest in his temporal and spiritual welfare. You are cast on the world with a parchment authorising you to practise on His Majesty's subjects. You require a knowledge of disease, but you also want to learn how to deal with men. There is much truth in the saying that to travel round the world is a more valuable asset to a medical man than the M.D. of any university. There are no lectures on savoir faire given in the schools. One of the first patients I saw in private practice was a man with a small carcinoma of the tongue, and as he seemed to hesitate about its removal it was agreed that a consultation should be held with Sir James Paget. After the examination of the patient Sir James took me into another room and to my utter surprise said, "I agree with you entirely, the case is a most favourable one for operation, but I have long made a study of men, and this man belongs to a rare type which invariably refuses operation, however earnestly we or other surgeons may advise consent." And it was so; Sir James Paget's eloquence broke on a stubborn reef and this patient was never operated on. Tact will sometimes succeed when without it the surgeon is powerless. I remember many years ago a patient very ill with strangulated hernia was addressed in a melancholy voice by a surgeon in these words: "I am very sorry to say that I shall have to operate on you"; the patient promptly replied: "You need not be sorry, I will not have any operation." Another surgeon came on the scene and after chatting for a while with the patient said: "This rupture must be put back, but I shall have to give you a little chloroform"; the patient immediately responded, "Thank you; please do it at once." This incident shows how a gloomy manner and an unhappy choice of words may be prejudicial to a patient. Solomon says, "Death and life are in the power of the tongue." "Operation," "cancer," and some other terms excite in some patients resistance or needless dread; and we should, when seeing a patient for the first time or in cases of serious illness, avoid using "such Ethiop words, blacker in their effect than in their countenance."

The man who thinks only of his patient as an interesting pathological specimen does not succeed in practice. Think of the tragedies and sadness which day by day we witness. The relations and friends want to know, not whether an interesting post-mortem examination may be expected, but what are the chances of recovery. Devote yourself without stint of time and trouble to your patient. Never give in, however grave and hopeless the illness, while life lasts, and you will have your reward and rightly and surely win the affection and esteem of the whole neighbourhood. In the despair of illness, even when "life is set at a pin's fee,"

"to labour in his vocation" till that "the fire of life kindle again" or the hour arrives when

44 Labouring Art can never ransom Nature From her inaidable estate."

Every man is a debtor to his profession. A vast field of our art and science still remains unmapped and unexplored. Let it be your ambition to contribute something to the slow but certain advance of medicine. Though in this as in every other branch of science each stage is associated more particularly with one or more great names which are inter-woven in its history, yet we ought never to forget those of less renown, the most obscure doctor who has accurately recorded an important fact, he also has added his stone to the building. It not seldom happens that before qualifying for practice a student becomes interested in some problem which he determines as soon as time and opportunity offer to investigate. It was so in my own case. I trust that some of you will take up research work, for you will then add greatly to the interest and satisfaction of your life, and you will be fulfilling that sacred duty laid upon us all of adding one more stone to the building. Nothing can exceed the zest to life that such work gives. The joy of research work is, like that of religious belief, incommunicable from one person to another. Seize the occasion, do not delay, for in later years other duties may imperiously interpose, other work may fetter you in its prison, or strength may fail.

The attempt to solve one problem you will soon find determines the opening up of many others. The majestic range of science and the littleness of all our knowledge will dawn upon you. You will be brought face to face as a humble investigator with the problems of science, illimitable and inexhaustible, which await solution. You may attain the thrill of delight which accompanies the first perception, the slow unfolding of some new truth or principle. Though awed and amazed by the wonders that extend far beyond your vision, do not be discouraged by what may appear but as a puny effort on your part. Take courage and resolution from the words of Paracelsus :-

"So that when, qualling at the mighty range
Of secret truths which yearn for birth, I haste
To contemplate some one truth,
Its bearings and effects alone—at once
What was a speck expands into a star,
Asking a life to pass exploring thus,
Till I near craze. I go to prove my soul!
I see my way as birds their trackless way. In some time, His good time, I shall arrive. He guides me and the bird—in His good time."

The life of the doctor is so closely bound up with all the most intimate phases of human life, it touches so closely the finest and deepest chords of the life of man, that it is not surprising that literature teems with references to our pro-Often in the most satirical and humorous descripfession. Often in the most satirical and humorous descrip-tions of the doctor's life there is some underlying truth which makes the satire or the humour all the more pungent. Dr. Sangrado combined a glib tongue with very active methods of treatment. No one could say of him as we can of the charlatans of the present day that-

"Mere prattle without practice was all his soldiership."

In appearance Dr. Sangrado was tall and withered. He is described as the learned forerunner of the undertaker. His routine diagnosis was obstructed perspiration. His staple remedies were drenching and bleeding. He believed it was a mere vulgar error that the blood was of any use in the system-the faster you draw it off the better. To live, he said, is merely not to die. A patient has no more occasion for blood than a man in a trance. It is recorded that Dr. Sangrado despatched business so fast that the fraternity of notaries who made wills found half their jobs spoiled, as they could not keep pace with him. Notwithstanding all this farrago of nonsense, it is true that in certain cases bleeding is an excellent remedy, and that drenching is patronised yearly by the fashion who overeat themselves now, as they did in Valladolid, in Sangrado's time, during most of the

In the case of Mr. Pilgrim the satire is directed against his commercial instincts. Mr. Pilgrim's estimate of even a confiding patient was apt to rise and fall with the entries in the day book. He was known to have discovered the most unexpected virtues in a patient seized with a promising illness. A good inflammation fired his enthusiasm, and a action, not inaction, is comfort. It is the doctor's privilege | lingering dropsy dissolved him into charity. Gradually, as

his patients became convalescent, his view of their characters became more dispassionate; when they could relish mutton chops he began to admit that they had foibles; and by the time they had swallowed their last dose of tonic he was alive to their most inexcusable faults.

Passing from this sordid view, we have in the "Crown of Wild Olive" a noble statement of our relation to the necessary but always difficult question of fees: "A good soldier mainly wishes to do his fighting well. He is glad of his pay—very properly so—still his main notion of life is to win battles, not to be paid for winning them. So of doctors. They like fees no doubt-ought to like them; yet if they are brave and well educated—the entire object of their lives is not fees. They desire to cure the sick; and if they are good doctors, and the choice was fairly put to them, would rather cure their patient and lose the fee than kill him and get it. And so with all other brave and right-minded men: their work is first, their fee second—very important always, but still second. This is no small distinction. It is between life and death in a man; between heaven and hell for him. You cannot serve two masters: you must serve one or the other. If your work is first with you, and your fee second, work is your Master, and the lord of work, who is God. But if your fee is first with you, and your work second, fee is your Master, and the lord of fee, who is the Devil; and not only the Devil, but the lowest of Devils-' the least erected fiend that fell.' So there you have it in brief terms; Work first—you are God's servants; Fee first—you are the Fiend's. And it makes a difference, now and ever, believe me, whether you serve Him who has on His vesture and thigh written 'King of Kings,' and whose service is perfect freedom; or him on whose vesture and thigh the name written, 'Slave of Slaves,' and whose service is perfect slavery."

It is a solemn and momentous fact that no individual in the world stands alone: "For none of us liveth to himself and no man dieth to himself." Let us always remember this in our relations with patients and others with whom we are associated. It is in the bearings of our words and acts on the lives of others that the solemn responsibility of human existence lies. The ripples produced by the casting of a pebble into the sea will theoretically never cease.1 Resolve then that your words and actions which start enduring ripples and eddies in the lives of others may be without spot and blameless. Wisdom is the principal thing, so let your influence lead to the love of wisdom, for is it not written that "She is more beautiful than the sun, and above all the order of the stars: and being compared with the light she is found before it, she is the brightness of the everlasting light, the unspotted mirror of the power of God, and the image of His goodness."

There is one word more I should like to add before concluding these remarks. The pathway of medicine is like the pathways of all other departments of life, in which the lot of man is cast. The student pilgrim of medicine has a free choice offered to him. It is the old old story of the choice between good and evil. None of us are exempt from the dangers and temptations of life. Pallas Athené in her legendary address 2 to Perseus demands an answer to the question as to which of two sorts of men are more blessed. "I am Pallas Athené; and I know the thoughts of all men's hearts, and discern their manhood or their baseness. And from the souls of clay I turn away, and they are blest, but not by me. They fatten at ease, like sheep in the pasture, and cat what they did not sow, like oxen in the stall. They grow and spread, like the gourd along the ground; but, like the gourd, they give no shade to the traveller, and when they are ripe death gathers them, and they go down unloved into hell, and their name vanishes out of the land. But to the souls of fire I give more fire, and to those who are manful I give a might more than man's. These are the heroes, the sons of the Immortals, who are blest, but not like the souls of clay. For I drive them forth by strange paths, that they may fight the Titans and the monsters, the enemies of Gods and men. Through doubt and need, danger and battle, I drive them; and some of them are slain in the flower of youth, and some of them win noble names, and a fair and green old age." There are still Titans and monsters to be grappled with in the spiritual and secular world, and splendid victories to be won by the students of

medicine by industry and faith over disease and death. May it be your resolve to answer with Perseus: "Better to die in the flower of youth, on the chance of winning a noble name, than to live at ease like the sheep, and die unloved and unrenowned."

The love of knowledge is natural to man. I may add that so also is the love of goodness. In the competition of life it is well to try to think always the best: not the worst of your companions and contemporaries. "Suspicions among thoughts are like bats among birds, they ever fly by twilight. Sir George Humphry's variation of the motto "Evil be to him who evil thinks" contains a great truth: "Good will be to him who doth good think." If evil is born in us, it is equally certain that we are the inheritors of a principle of goodness. "False prophets have told us for centuries that men are nothing but fiends or wolves, half beast, half devil. Believe that," says Ruskin, "and indeed you may sink to that. But refuse that, and have faith that God 'made you upright,' though you have sought out many inventions; so you will strive daily to become more what your Maker means you to be—and daily gives you also the power to be—and you will cling more and more to the nobleness and virtue that is in you, saying 'My righteousness I hold fast, and will not let it go.'"

In this great city the sweetest story of an ideal doctor's life was written.3

"Not once or twice in this rough island's story The path of duty was the way to glory."

The Drumtochty doctor won his way to glory, but the story of his life is but one example of the sympathy, the selfsacrifice, and the essential goodness exhibited in the lives of thousands of men who have ennobled that profession on the threshold of which you stand. The Drumtochty doctor didna' trouble the Kirk often; but in the path of duty and The Drumtochty doctor charity he did his best, regardless of reward, in the cold and in the heat, in mist and in rain, in winter storm and in biting winds, through peat bogs, and through snowdrifts, and through rushing torrents, year in and year out, for every man, woman, and child, in the wild straggling district in which he practised.

"The sweetest canticle," says Bacon, "is Nunc Dimittis, when a man h a attained worthy ends and expectations. May each of you here have that sweet music as your reward. Wherever y'ur lot may be set and under all the changing circumstances of time the bed-rock principles of an ideal life remain unchanged. Let me, then, commend to you the life and character of the Drumtochty doctor. He went about doing good and healing the sick. He visited the fatherless and widows, and kept himself unspotted from the world, thus practising that pure religion and undefiled which won for him, and which may win for you and for me, as we pass into the silent world, the answer from the King: "Amen dico vobis, quamdiu fecistis uni ex his fratribus meis minimis, mihi fecistis."

THE OPERATIVE TREATMENT OF CATARACT.1

BY A. E. J. LISTER, M.B., B.S. LOND., F.R.C.S. ENG., CAPTAIN, INDIAN MEDICAL SERVICE.

I. EXTRACTION OF CATARACT IN THE CAPSULE.

So much has been written on this subject that I fear it is difficult to add to it much of interest. However, as few writers with any considerable experience of the operation, except Major H. Smith, I.M.S., of Jullundur, have recorded their actual experience, I think it is of value for other operators to place their experience on record. My experience is based on 576 cases operated on by me, chiefly at the Civil Hospital, Jullundur, where I had the privilege of working for a year under Major Smith. 81 of these cases were done at the Cantonment General Hospital, Meerut.

General Results.

Suppuration occurred in two cases, leading to total loss of the eye. One of these disasters occurred in a case in which I had to introduce a spoon to extract the lens owing to vitreous appearing at the upper edge of the wound whilst

 A paper read at the Bombay Medical Congress, February, 1909.
 Q 2

attempting to extract the lens. Suppuration at the site of the wound occurred in two cases, due, I think, to infection at the first dressing, as it was left to a compounder. One of these cleared up and caused no after-effects at all. The other did not clear up readily, but curiously enough caused scarcely any pain, and the patient left hospital on the eleventh day to proceed home, thinking he was all right. I am unable to say whether the result was a permanent damage to the eye. This gives a percentage of 0:34 per cent. of eyes definitely lost by suppuration. I attribute this low percentage to the use of the 1 in 2000 perchloride of mercury There is no doubt that this lotion is a strong one to use for douching the eye, as I can vouch for from personal experience of it. I had my own eye douched with it as I happened to get some pus into it. It caused me such pain that I could not open my eye for a time, and it remained painful for four hours afterwards. Of course, it must be borne in mind that the patients are all under the influence of a 4 per cent. cocaine solution, and do not, as a matter of fact, complain of more than a little pain, and that it is a potent factor in preventing suppuration I think is undoubted, as very few indeed of these cases were given any preliminary treatment for the conjunctiva. I would not have operated on some of them had I not learned from observation at Jullundur that it was safe to do so if one used the douche. Slight keratitis occurred in two cases, which yielded readily to treatment by a saline purge and pilula hydrargyri internally. No cases of intraocular hamorrhage occurred in my cases. No case of iritis was seen at all.

Lacrymation —Troublesome lacrymation occurred in several cases, but usually yielded readily to treatment by instillation of weak zinc sulphate and boric acid drops. In one case, which was not relieved at all by this treatment and which persisted for a fortnight, relief was obtained by ordering the patient to douche the eye freely with cold water twice a day.

Marked injection of the conjunctiva with lacrymation occurred in a certain number of cases. I attribute it chiefly to an excess of the 1 in 2000 perchloride lotion left in the conjunctival sac. It yielded readily to local treatment. If any marked pain was present leeches were always applied and invariably gave relief.

One complication of great interest occurred, and I have not heard of a similar one. A man, aged 73 years, an intelligent carpenter, was operated on by me for an ordinary mature senile cataract. His pupillary reaction was normal and projection of light perfect. The cataract was extracted in the capsule quite easily without any complication whatever. When the eye was opened for dressing on the fourth day the man said he could not see fingers held in front of the The cornea was clear and the eye looked perfectly normal. The wound healed normally and the progress of the case was in every way normal, but he was never able to distinguish more than the movements of the hand in front of the eye and left the hospital after 17 days in this condition. Before leaving the hospital the fundus was examined but appeared normal. I was quite unable to understand why he could not see, and particularly asked him to come back again later to report progress. About three and a half weeks later he came to my house looking extremely pleased and walked into the room obviously seeing, as his other eye had been lost. He stated that a week before his sight began to come back and in three days was completely restored. That is to say, after a period of three weeks, during which he could only see hand movements, his sight was completely restored. I had no time to estimate his refraction carefully but his vision was excellent, and I have no doubt will be \$ when his cornea settles down. The fundus was quite normal. It is not possible to say what was the exact cause of this condition. In the absence of a better explanation it seems possible that the removal of the lens entire, for it was a large one, may have had some effect upon the circulation of the retina, causing a temporary interference with its functions. The man's mental condition was quite normal, and there is no doubt as to the genuineness of the history, as he was a very intelligent carpenter, who could give an excellent account of his past services.

Escape of the vitrems. - In my series of cases escape of the vitreous occurred 29 times. In 22 cases it occurred during extraction of the lens in ordinary cataracts. In two cases it occurred during extraction of the lens, which had been previously dislocated by the "rawal" or native lens coucher. Including all cases this gives a percentage of 5.03. Taking

cataracts whose lenses were not previously dislocated, this gives a percentage of 4.7 approximately. The only serious complications, due to the loss of the vitreous in my series. was drawing up of the iris, leading to occlusion of the pupil in one case. The eye has recovered, and I propose making an artificial pupil for the patient, who is still under treatment. In most of the other cases the escape of the vitreous caused no trouble at all, but in a few cases the patient suffered from lacrymation due chiefly to the edge of the iris being caught in the wound. In two cases the edges of the iris had to be snipped off. In one case, that of a very old woman, considerable flattening of the cornea resulted, and I was in despair of it getting right. In six weeks' time, however, it became all right, and she was anxious to have the other eye operated on. I am in favour of using a pad sufficiently large to exert mild pressure on the eye in cases in which escape of vitreous has occurred. In one case where this was not done I noticed when the eve was opened on the third day that the cornea at the lower edge of the wound was bent away from the upper edge and the wound gaping. This was due to a very nervous patient "squeezing" at the time of operation and after. The wound healed quite well but the iris was drawn up, occluding the pupil as described before. It is interesting that although the wound was open wide on the third day no suppuration occurred, and it healed soundly when a firm pad was applied.

The percentage of escape of the vitreous in the operation undoubtedly decreases with the experience of the operator and—a point upon which I wish to lay stress—the experience of his assistant. The first point is well illustrated by my own experience. In my first series of 63 cases at Jullundur in the spring of 1907 escape of the vitreous occurred in six cases, whereas at Jullundur in 1908 I did 64 non-selected cases in two days with only one slight escape of the vitreous in one case. In this case, moreover, the patient squeezed out the lens with a little vitreous on completion of the incision. The second point is illustrated by my Meerut experience in 1908. In a series of 81 cases I had escape of the vitreous in seven. I had to start operating with assistants who had no previous experience of eye operations at all and very little of surgery. I should mention also I was handicapped by having to operate out of doors for the first 40 cases owing to want of proper light. I am quite sure that had I had a good assistant at least half of the escapes of the vitreous would not have occurred. I think, therefore, it is impossible to lay too much stress on the importance of fully training your assistant. Every operator should if possible first act as an assistant himself to become fully familiar with all the details. When seeing a really good assistant at work one hardly realises what an important part he plays in the operation. It is only when having to train one for personal aid, particularly if he be not too intelligent, that the importance of his part and how much damage he can do are realised. He should be taught that not only should he keep the orbicularis muscle well under control, but that when placing his thumb in position for this purpose he should draw up the loose skin of the upper lid so as to keep the eyelids well open. If he does not do this the operator will not have such a good view of the field of operation—a very important desideratum. He should be taught that he must always watch the patient's expression, and the moment the patient shows any sign of straining he should take hold of the speculum lightly and be prepared to raise it, so as to prevent the patient putting pressure on the eyeball by closing of the lids and causing escape of the vitreous. A good assistant will anticipate this and avert it.

Results as regards vision.—It is quite impossible to give a statement of the exact vision obtained by every patient operated on in Indian hospitals in the provinces. Jullundur, owing to deficient accommodation, the patients are allowed ordinarily to leave the hospital on the sixth day. The eye is still weak and cannot tolerate light well enough to allow the vision to be tested at a distance. In Meerut my patients are discharged on the tenth day, but that also is too early to allow their vision to be tested other than roughly. I show the patients groups of small dots, varying in size from one readily seen down to one as big as the ordinary full stop in print. They are asked to count these with a + 10 D. lens. If they can count down to the last size but one I am sure from experience their vision will be about \$ when the cornea has settled down. This may not appear very scientific, but it is all one can do and it is for all practical purposes

sufficient. I have had the opportunity of seeing and testing many cases of my own and of Major Smith which came back for various reasons, and from an experience which is based on certainly not less than 250 of these cases, I should say that the average vision obtained after this operation, provided the eye was healthy before operation, is \$.

Astigmatism.—I have worked out the refraction of a number of cases and find the resulting astigmatism is usually from +0.75 D. to +1.0 D. To European ideas this statement of results will appear unsatisfactory, as it has not the usual table giving the vision obtained by each case. To those, however, who know the East, and that the native of India is as well able to appreciate the value of an operation as the people of other countries, seeing that he judges by the result only, which after all is the essential point to people of any nationality, the fact that in six months (and that broken up into two periods through enforced absence) I was able to get 81 people to come forward for operation, will appeal as an argument of the first importance. It should be mentioned that this was in a small cantonment hospital, where no eye work at all had been done in the preceding year, and that all around are found in every station operators for cataract by the ordinary method of wide experience. Had my results been worse than those of others near me, no one who has any knowledge of India will deny that my cases would have fallen off as the results became known.

I will now make a few remarks on certain points of importance in connexion with the operation.

Technique. - My technique was exactly that of Major Smith, to whose kind tuition I owe almost all that I know of this operation; it has been fully described already, so I shall not describe it here, but a few observations on matters which my experience suggests may be of interest. I think that the most important thing in the operation is for the operator to have an exact knowledge of the particular way in which to extract each class of cataract. It is extremely difficult to give a description of the different classes of cataracts classified from the point of view of the operator. It is quite easy to point them out clinically, and I cannot too strongly emphasise the importance of the operator being able to tell at a glance which class of cataract he has to deal with, and how it will behave. For instruction on this point I advise him to see Major Smith's book, which is coming

out shortly, as space forbids me to go into it here. I strongly recommend anyone commencing to do this operation to spend some time with a surgeon who has a large clinique, and to acquire this knowledge practically, which, in my opinion, is the only satisfactory way. The knowledge doubtless can be acquired by an intelligent operator by actual experiment, a course which is, however, fraught with danger to the patient—a fact which is obvious when we read of the experiences of operators in America and elsewhere who have tried this operation without a full practical knowledge of the details. It does not surprise me at all that they condemn it and give it up. I admit at once that the operation is more difficult to learn and more dangerous to the patients in the hands of a beginner than is the ordinary operation. I consider, however, that in the hands of an experienced operator the freedom from complications, the avoidance of a secondary operation, and the better vision obtained are of such importance as to render it the ideal operation. When the fact that immature cataract can be operated on at any stage with absolute safety is taken into account, thereby saving patients sometimes years of weary waiting, and, as sometimes happens, loss of sight whilst waiting, from glaucoma or other diseases (an occurrence which I have seen several times myself), I think the advantages of this operation are so enormous as to render it the most important advance in ophthalmic surgery since the time of Daviel. To estimate the value of knowing the exact method of procedure in this operation, I may mention that on several occasions when operating at Juliundur, where both eyes are usually operated on at the same time, I have extracted the lens and had escape of the vitreous; the fact has been pointed out to me that I failed to modify the technique quickly enough. Major Smith has then operated on the other eye to show me where I had failed and has had no escape of the vitreous at all. Both eyes almost always, if the cataract be of the same degree of maturity, behave in the same manner in this operation. One of the ways in which escape of the vitreous occurs and may be prevented is in the operation for fairly immature cataracts. These cataracts are usually vomiting and do not advocate the general use of chloroform,

extracted by dislocating the upper edge first, which comes first through the wound. The operator by pressure directed backwards dislocates the lens and keeps the pressure up, but the lens does not come out. If the pressure be continued, as it must be, and the lens does not emerge, the vitreous may appear above the upper edge of the lens. If when the vitreous is seen in this position the pressure be still kept up, but its direction instantly changed so as to cause the lens to be carried upwards and its posterior surface to pass over the posterior edge of the incision, the escape of the vitreous will be averted. Escape of the vitreous occurred in this way two or three times to me whilst operating before I learned to modify my technique instantly so as to avert it. Sometimes the manœuvre has to be combined with counter pressure with a flat spoon above the wound. It is by slight variations of technique such as this, which are carried out by the experienced operator almost automatically, that the various difficulties which arise are overcome and escape of the vitreous and other accidents are avoided in this operation. operator who is able to anticipate the various modifica-tions of technique required in the course of the operation is the one who will have the best results. doubt as to how a particular cataract should be extracted, my opinion is that the safest way to proceed is to see if the lower edge of the lens can be dislocated first and the cataract made to turn over and come out with the lower edge first. This is done by pressing with the strabismus hook over the lower third of the cornea with a moderate pressure, the direction of the pressure being towards the patient's feet. If the lens is going to turn over, the lower edge will be seen commencing to dislocate and should not be hurried. As it dislocates, the pressure with the hook should be changed to the upward direction and the lower edge of the lens be followed up, to help it out and prevent its falling back again. If, however, it is not going to turn over and the upper edge of the lens dislocates first, the direction of the pressure should be immediately carried backwards and upwards, following up the lens as it passes out through the wound. It is the failure to instantly change the direction of the pressure and to modify its degree which accounts so often for escape of the vitreous and bursting of the capsule in this operation.

The importance of quickness. - I think it is very important, if the patient is very nervous, and particularly if a woman of the higher classes in India, who are I find usually very nervous, to extract the cataract as speedily as possible. I find I am most liable to get escape of vitreous in this class of case. It has occurred to me several times, whilst extracting one of the large white-looking mature lenses, which have to be extracted lower edge first, as previously mentioned, that all has gone well until the slow pressure of the lens turning over has pressed on the iris. Pain results, the patient strains, and if care is not taken the vitreous is very apt to be squeezed out, or the lens capsule to burst. I think the two best ways of guarding these occurrences in this class of case are: 1. To be sure you have a large enough incision. In a patient likely to give trouble I take care to give plenty of room for the lens to slip out easily. If the incision be made a shade larger than usual the lens comes out more quickly, a very desirable thing in patients with small self-control. 2. I have lately given obloroform in these cases. I was led to try it first by having a "purdah nashin" woman of a highly nervous type brought to me for operation. Her other eye had been unsuccessfully operated on by the ordinary operation elsewhere. I concluded she had behaved badly at the time of operation, and that she would do so for me. I decided to give chloroform. I had no difficulty and the case did perfectly. I think I should have not succeeded so well without chloroform. This case led me to try chloroform in other cases of the same class with equally good results. I have done too few to be able to come to a definite conclusion, but I think chloroform merits further trial. I put the patient fully under, completing all preliminary preparations as she is going under. I operate the moment anæsthesia is complete. The eyes are usually turned up, but this does not cause the least difficulty in this operation. The patient soon comes round, and usually is allowed to go to sleep if possible, as there is then less liability to vomiting, I find. The patient should, of course, be carefully watched until the anæsthesia passes off. I am fully aware of the increased danger of intraocular hæmorrhage from but it has been of great service to me in the class of case mentioned, and I mention it for that reason.

Iridectomy.—I prefer always to do an iridectomy. skilful performance of the iridectomy is of special importance in this operation, as you have a large wound and greater liability of the vitreous to escape consequently. should be very lightly caught; in fact, scarcely held at all by the forceps, as it is a sticky membrane and adheres to the forceps. If squeezed, the patient is very liable to strain and force out the lens or vitreous, or both. The edges of the iris are rather liable to prolapse, even when they have been carefully replaced, owing to the large wound. This may be suspected if the patient complains of excessive lacrymation when the eye is dressed. If very small the prolapse may be left alone, but if large the eye should be cocainised, and gently washed out with boracic lotion. The upper lid should be raised by an assistant by means of a strabismus hook and the projecting piece of iris snipped off with a sharp scissors. The lacrymation will soon cease if this be done, and the eye will settle down and give no further trouble.

II. THE AFTER-EFFECTS OF ESCAPE OF THE VITREOUS DURING THE OPERATION OF EXTRACTION OF CATARACT IN THE CAPSULE BY SMITH'S OPERATION.

In the various discussions which have taken place from time to time, as to the advantages and disadvantages of this operation, it has been contended by the opponents of the operation for the extraction of the cataract in the capsule that one of the chief objections to this operation is the frequency of escape of the vitreous. This being the only complication which is at all frequent, and the one which is most commonly met with by beginners in this operation, I inquired from Major Smith on my arrival in Jullundur in 1906 if any series of cases had ever been published in which the after-effects of escape of the vitreous in this operation were given. Major Smith informed me, that as far as he was aware, no such series of cases had ever been published either after this or the capsulotomy operation. I then offered to undertake a research into the subject and received permission from Major Smith to make every use of his hospital records which were placed at my disposal for this purpose. Every assistance was rendered me by Major Smith, whom press of work alone had prevented from carrying out this work before. Many thousands of cases in the operation books were gone through and the names of patients in whose eyes escape of the vitreous had occurred were noted. Each patient was then written to, and of them 95 presented themselves for examination. In certain of the tables it will be seen that the amount of vitreous and the remarks made at the time of operation are not given. The reason of this is that in the operation book a note only was made of the fact that vitreous had escaped. The details are noted by Major Smith on the patients' tickets always under four headings: (1) drop = 2 to 4 minims; (2) trace = 4 to 5 minims; (3) slight = 5 to 10 minims; and (4) some = 10 minims to one-third of the vitreous. The cases will be found classified in the tables appended under these headings.

As the cases went back as far as nine years, it is not surprising, considering the many thousands of hospital tickets there were, that all the tickets could not be found. Native patients are very apt to take the ticket home with them when they go, and in a large hospital with many hundreds of patients and a very small staff, such as there is at Jullundur, it is not always possible to prevent this. Some patients being satisfied with their condition do not wait to be discharged, but depart, taking the tickets with them. These facts will be well known to surgeons in India, but they are mentioned to make the matter clear to any who do not know India. Three were found to have had escape of the vitreous in both eyes, so the number of eyes examined was 98. In 90 of these cases no portion of the capsule of the lens was found to remain; in eight a portion of it or the whole was found to be present.

Method of Examination.

The vision of the patients was tested by Snellen's testtypes, if they were able to read; in the case of those unable to read, who formed the bulk of the cases, by

Snellen's distant test-types, were kindly supplied for this purpose by Messrs. Lawrence and Mayo of Calcutta. I found it more convenient to cut out various groups of dots and to mount them on cardboard, one or two for each corresponding line of Snellen's test-types. dealing with patients lacking in education and advanced in years, this plan will be found an advantage. I have many times tested the results given by the same people when asked to read the Snellen's test-types. I find that on the whole the dots are slightly the harder test of the two, so that all the results given may be taken as absolutely correct. I found the use of these dots more convenient than Landolt's optotype, which I also used for some cases. At first I endeavoured to test the vision with the glasses found by determining the refraction of each case by retinoscopy. I found after doing a number of cases that the astigmatism was scarcely ever over one dioptre, so to save time I gave up doing a retinoscopy in every case, and gave them the plus lens they preferred, which in almost every case was a plus ten dioptre lens. The excellent results obtained proved the correctness of my observations, as the results obtained were all without the use of cylindrical lenses. I have noted in the column of remarks the cases in which the spherical lens other than + 10.0 D. was

The patients in most cases insisted on returning the day they arrived, so that on account of press of work I was unable to do a retinoscopy in the majority of the cases. As excessive astigmatism has been alleged to be caused by this operation, it may be well to call special attention to these facts. I have also observed a number of cases in which escape of vitreous had not occurred, and I found that in them also the average astigmatism was one dioptre. Owing to enforced absence on several occasions 25 of the cases were kindly examined for me by Major Smith. I had also the advantage of the opinion of Major Smith on the few cases in which disease of the fundus was present, which will be mentioned later. The chief facts revealed by this research are as follows. The total number examined was 98; in no case was any detachment of the retina present. Disease of the fundus was found to be present in eight eyes. A detailed account of these is given. The exact time which had elapsed since the operation was known in every case. It averaged 3.706 years. The different periods since the time of operation ranged from six months to nine years.

Vision of Cases.

Tables will be found at the end of the paper giving the exact vision of each case, with one exception, in which by an oversight I forgot to note it at the time of examination. It may be wondered why the vision of the cases in Table A does not quite correspond with that of those in Table B, being in the form shown chiefly as ; the answer is that at first I did not test a patient further if he had a vision of §. Later, when I found what excellent vision they had, I endeavoured to estimate it exactly. It will be noted that the average standard of vision is very high indeed; thus in 61 cases in which there was no opacity of the cornea, capsule left behind, or disease of the fundus, it will be found that the vision was as follows:

$$\frac{6}{3} = 4, \quad \frac{6}{3 \cdot 5} = 6, \quad \frac{6}{4} = 4, \quad \frac{6}{4 \cdot 5} = 5.$$

$$\frac{6}{5} = 4, \quad \frac{6}{6} = 33, \quad \frac{6}{8} = 2, \quad \frac{6}{9} = 3.$$

I may remark here that I find in India, owing to, I think, the better light and clearer atmosphere, the patients who come to me for examination usually read a line or two more of the Snellen's test-types than they do in England. I find

very many British soldiers read $\frac{6}{3.5}$ quite readily. This may

account to a certain extent for the excellent vision of these cases, but it is not the chief reason, which is the absence of an after-cataract, leaving a perfectly free pupil and also the low degree of astigmatism. An important question is, Does the amount of vitreous lost exercise a marked effect on the vision obtained by the patient? The figures at my disposal are too small to admit of any definite conclusion, but they indicate, as far as they go, that it does not have any marked groups of dots, which they were asked to count. Special influence. Reference to the tables shows it does not appear test-cards, with dots of various sizes, corresponding to to have any marked influence. Thus we find in five cases in

which the largest amount of vitreous is lost the vision was :--- $\frac{6}{3}, \frac{6}{5}, \frac{6}{6}, \frac{6}{6}, \text{ and } \frac{6}{9}.$ "Trace" and "Slig Taking six and "Slight" we find the vision to 6 6 6 6 5' 6' 8' 9 6 6 The number of cases is far too 3' 3.5' small to be conclusive, but they are sufficiently striking to point out the need of further investigation on this point. Thus it does not appear from these cases that the amount of vitreous lost, provided that the eye recovers from the immediate result of the operation, is the important factor in determining the ultimate vision of the patient that might be

expected. I repeat that the number of cases is too small to be conclusive, but they are sufficiently striking to call for further investigation. Those operators who have observed cases in which a large amount—i.e., more than one-third—of the vitreous has been lost will have noticed that the vision of such patients is often much worse at the time of leaving hospital than the vision of those patients in whom a smaller amount has been lost. I have had the opportunity of observing these patients in a number of cases after leaving hospital, and have come to the conclusion that the vision of these patients is eventually much better than one might expect at the time of their leaving hospital; this observation is in accordance with the above facts, and will be of interest to those who may be intending to adopt the operation of extraction in the capsule. I think it is due to the greater distortion of the cornea which results temporarily, and to the fact that the normal tension and conditions of circulation and nutrition of the eye take longer to be re-established after loss of the vitreous than when it is not lost. I have noticed this to be particularly the case in very old and feeble patients. This fact may have led ophthalmologists who have not had the opportunity of seeing the number of cases in which escape of the vitreous has occurred, at a time when the eye has had sufficient time to completely recover, to regard escape of the vitreous as more serious than this paper tends to prove it to be.

Cases in which Disease of the Fundus was Present.

In eight eyes of the 98 cases examined disease of the fundus was found to be present. It may be of use to future observers to mention these in detail. They will be found in Table E. I will proceed to make a short comment on each:-

CASE 1 .- Is one of syphilitic disease of the fundus and needs no comment.

Case 2.—Presents the ordinary history and signs of malarial optic neuritis. I have seen many cases with a similar history and fundus condition. Major Smith says it is quite common in the Punjab and my smaller experience coincides with this.

Case 3.—Is an ordinary case of disseminated choroiditis. As it was present in both eyes, and escape of the vitreous only occurred in the right eye, it cannot be attributed to escape of the vitreous fairly. To discuss the question fully as to whether the condition of the fundus was caused by the extraction of the lens in its capsule, as may be suggested by the opponents of this operation, is beyond the scope of this paper. I will only say in passing I do not think it was. Disseminated choroiditis is so commonly seen in the Jullundur clinic that I do not see any reason to connect it with the operation.

CASES 4, 5, and 6.—These were all cases in which the lens had been previously "couched" and presented the typical appearance of the condition, which always follows couching of the lens. This condition has been described fully in the medical press by Major Smith. It is interesting to note, however, that apparently in some cases at least removal of the lens does not prevent the progress of this serious condition.

CASE 7 .- Is a case of bilateral optic atrophy. Escape of the vitreous occurred in one eye only, so it could not have been the cause of the condition in one eye, and it is reasonable to assume it did not cause it in the other. It may be said that the optic atrophy was caused by the operation for extraction of cataract in the capsule, in both eyes. The disease is such a common one in the Jullundur clinic in old men that I think it is quite as reasonable to say it was unconnected with the operation as with it. This matter needs a separate investigation. It should, however, be noted here, in connexion with this and the preceding case, that Major Smith always extracts a cataract if there is any hope of improving the vision for a time and that the condition may have been present in its earliest form at the time of operation.

In Case 4 the condition may possibly have been caused by the escape of vitreous, but as the eye was operated

on five years before and as the vision was 16, when seen, it seems, taking into consideration the fact that in no other case in the series has any effect been proved to have followed escape of the vitreous, that it is quite as likely to have had another cause. On examining these cases critically it will appear that the case mentioned last, Case 4, Table E, only may be due to escape of vitreous. This condition, however, I have seen so commonly in the Jullundur clinic that I do not regard it as being due to less of vitreous. Major Smith shares this opinion. I, however, leave the truth of this opinion for other observers to prove or disprove. It may be argued that the cause of some of these conditions may, if not loss of vitreous, be due to the disturbance of the conditions of the eye caused by the extraction of the cataractous lens in the capsule. This argument, I think, can only be advanced as regards two of the cases. Optic atrophy and disseminated choroiditis are very common conditions in patients attending the Jullundur clinic, and I regard these cases as attributable to ordinary causes, but on this point also further investigation is required. We arrive therefore at the conclusion that of the series of 98 eyes examined one case of retinal degeneration may possibly be due to loss of vitreous, or to the operation of extraction of the cataractous lens in the capsule, or to a combination of the two, and that one case of optic atrophy and one disseminated choroiditis may possibly be due to extraction of the cataractous lens in the capsule. If we take the escape of vitreous occurring during this operation as being about 5 to 6 per cent. in the hands of skilled operators and allow that one case out of every 98 in which this accident happens develops subsequent disease of the fundus, we arrive at the conclusion on the foregoing facts that loss of vitreous in this operation, provided the eye recovers from its immediate effects, is not the serious complication which it at first sight appears. It is interesting to note that this is the opinion arrived at by Major Smith from a general experience of these cases, apart from any definite research in this subject, some years ago.

It is specially interesting to note that detachment of the retina, the condition so generally feared as liable to occur after escape of the vitreous, did not occur in a single case. I suggest, in conclusion, that those ophthalmologists who state that loss of vitreous is such a serious accident in cataract operations have been guided by the facts as known to them in operations other than in which the cataractous lens is extracted in its capsule. It is quite probable that the eye in these operations hampered with débris and the capsule of the lens, which apart from those cases in which definite iritis occurs, must usually cause some degree of irritation, does suffer more serious damage when loss of vitreous also occurs than does the eye which is free from any irritating material. The fact that in the eight cases in which capsule was left there was disease of the fundus is interesting, but it should be remarked that in only one case was there a large amount of capsule—i.e., Case 10, Table C—the other cases having only a small amount as Major Smith always endeavours to remove as much of it as possible. On account of having a large wound it is possible to remove most of the débris, so that the condition in these cases was not quite the same as it is in the ordinary capsulotomy operation. Having regard to the facts given here, I maintain that though the number of cases is far too small to be conclusive it is sufficiently large to make

us hesitate before we accept any conclusions formed by ophthalmologists, who do not extract cataract by Smith's operation, as to the seriousness of loss of vitreous in this operation. Further investigation will doubtless throw more light on this important subject. I repeat, however, let as be careful before we accept any dicta by any ophthalmologist, however distinguished he may be, on this important subject, unless supported by a series of cases, an account of the operation performed, especially a statement as to whether the capsule was left behind or not, and if iritis or iridocyclitis followed.

The accompanying tables show (1) number of years since the operation; (2) vision; (3) amount of escape of vitreous; (4) astigmatism; (5) remarks noted on case sheet at time of operation; and (6) notes on points of interest in brackets in last column.

TABLE E.—Detailed Notes on 8 Cases (7 Patients, 1 Double) with Diseased Condition of the Fundus.

Case 1.—Name, B—. Operated on one and a half years ago.

"Drop" of escape of vitreous in both eyes—both extracted on spoon.

Vision = 4. States that he had very poor vision in both eyes before cateract developed. Had syphilis. On ophthalmoscopic examination signs of old neuro-re initis.

Case 2.—Name. Para Singh. Operated on five years ago. Vision Can only count fingers. Sight was all right for two years after operation. Then had high fever with delirium. Pupillary reaction very singgish. Disc pale. Retina strophied, probably caused by malarial orest neuritis.

Can only count fingers. Sight was all right for two years after operation. Then had high fever with delirium. Pupiliary reaction very singgish. Disc pale. Retina atrophied, probably caused by malarial optic neuritis.

Case 3.—Name, Utman Dai. Operated on one year ago. Vision: Can only see hand movements. Both lenses well extracted in the capsule with a "drop" of escape in the right. Disseminated choroiditis seen in both eyes on ophthalmosophic examination.

Case 4.—Name, Edoo. Operated on five years ago. Trace of escape of vitreous in right eye. Left eye lost previously from trachoma. Vision = 4. Very stupid old man. Could give no clear history of his condition. Retina presents appearance of retinitis pigmentosa sine pigmento in an early stage.

Case 5.—Name, Ram Singh. Operated on one and a half years ago. The right lens is noted as having been previously dislocated by the "rawal" or lens coucher at the time of operation. It was noted also as having been expelled on completion of the incision with a "drop" of vitreous. Note made "bad patient." Vision = f. On ophthalmoscopic examination the typical condition of retinitis pigmentosa sine pigmento, which always follows couching of the lens.

Case 6.—Name, Hako. Operated on two years ago. Vision: Ntl. Drop of escape in the left eye. Lens noted as dislocated at the time of operation. The same fundus condition as in Case 5, but more advanced. Case 7.—Name, Khuda Bux. Age 60 years. Operated on four and a half years ago. Bacape of vitreous in one eye only, amount not noted. Both lens extracted in the capsule. Primary optic atrophy in both eyes.

A REPORT OF SOME CASES OF VENOUS ANÆSTHESIA.

BY C. M. PAGE, M.B., M.S. LOND., F.R.C.S. ENG., SUBGICAL REGISTRAR, ST. THOMAS'S HOSPITAL; AND

S. G. MACDONALD, M.A., M.B., B.C. CANTAB., F.R.C.S. ENG.,

LATE HOUSE SURGEON, ST. THOMAS'S HOSPITAL.

Professor Bier, in April, 1908, read a paper at the German Surgical Congress entitled "On a New Method of Producing Ansesthesia in the Extremities." The procedure is applicable to either extremity, any part of which can be shut off from the general vascular system. The method consists essentially in the introduction of an anæsthetising fluid into one of the superficial veins of a given area of a limb, which area has previously been depleted of blood and isolated by tourniquets. The whole of the tissues of the isolated area ase in this way infiltrated by exudation of the medium from the capillaries of that area. The cases recorded by Professor Bier were chiefly operations on the upper extremity, only one case of amputation of the leg having been performed. We have employed the method for nine operations, seven of these being major amputations and most of them cases in which general ansesthesia was considered inadvisable.

is then firmly bound round the limb, from the periphery upwards, as high as the upper limit of the operation are Above this, and in contact with its last turn, is placed another rubber bandage, sufficiently tight to check the arterial circulation. The bandage covering the distal part of the limb is now removed, and a third bandage is wound firmly round the extremity at the lower limit of the operation area. This bandage must be tight enough to prevent diffusion of the injected fluid into the distal part of the limb. After a preliminary skin infiltration an incision a couple of inches in length is made across the line of the vein chosen in the leg, usually the internal saphenous. (This incision may be made at any convenient level, though Professor Bier advises that the vein be picked up in the upper part of the operation area.) The vein is isolated and a cannula tied into it firmly, as for an intravenous infusion. The cannula should be directed centripetally if the vein be opened low down in the operation area. if the vein be opened low down in the operation area, centrifugally if opened high up. Any small vessels that may have been divided are now secured to prevent leakage, and a good syringe of about 100 cubic centimetres capacity is attached by a short piece of pressure tubing to the cannula. The fluid is then injected gradually, a varying but considerable amount of pressure being required. As infiltration able amount of pressure being required. As infiltration occurs the area swells and turns dusky white in colour. Complete anæsthesia of the isolated area appears in from five to 15 minutes from the commencement of the injection. It may be accelerated by gentle massage of the part to facilitate diffusion of the fluid, or, if necessary, by the injection of more fluid. When anæsthesia is complete the cannula is removed and the vein is tied off. The skin incision, unless it falls into line with the operation incision, is sutured, and operative measures are then proceeded with.

This anæsthesia of the infiltrated area Bier terms "direct anæsthesia." After 15 to 30 minutes, however, from the time of injection the rest of the limb below the isolated area also becomes anæsthetic. This he terms "indirect anæsthesia." It is due to the establishment of a "block" in the nerve trunks as they pass through the infiltrated area. Indirect anæsthesia, however, seems to be of limited practical value, on account of the uncertainty of the time required for its completion. At the termination of the operation the upper bandage is slowly removed in order that vessels divided during the operation may be secured. If more than ten minutes be required for suturing the wound this bandage should be replaced, as sensation returns in the infiltrated area in eight to ten minutes after its circulation is reestablished.

Should an infective focus exist in the lower part of the limb to be operated upon it would obviously be inadvisable to bandage the whole extremity. In such a case the limb is first elevated, and then the first Esmarch bandage is placed entirely above the septic focus, extending centripetally from the lower level of the operation area. The hæmostatic bandage is next applied at the upper limit of the operation area, and, before removing the first Esmarch bandage, a third bandage is applied at the lower limit of the operation area. If the latter proceeding be omitted blood will regurgitate from below into the area to be infiltrated, and imperfect anæsthesia will result. It is of the utmost importance that the vessels in the operation area be completely emptied before the injection be commenced. With regard to the incision for finding a vein, it is obviously better in amputations either to make this in the lower part of the isolated area, or to make it in such a position that it will fall into line with the amputation incision.

A limit to the extent of the tissues which can be infiltrated is set by the undesirability of injecting more than a certain quantity of the ansesthetising fluid; 200 cubic centimetres of a 0.5 per cent. novocaine solution (which may be regarded as a maximum dose) should suffice to anæsthetise the field for most set operations; the area cannot conveniently be increased once operative procedures have commenced. As anæsthetic Bier recommends "novocaine" on account of its relative non-toxicity. A 0.5 per cent. solution in normal saline gives reliable results. We have used a 0.25 per cent. solution successfully in one case, though anæsthesia was somewhat more slowly produced. The amount injected varies with the size of the limb and the extent of the area to be infiltrated. From 50 to 75 cubic The details of the technique are as follows: the skin is centimetres suffices for a moderate-sized elbow, while 150 prepared in the usual manner; a sterilised Esmarch's bandage cubic centimetres are required for a knee area. More can

[†] Counts fingers only at 2 yards.

safely be employed in amputation cases, as only a small amount will subsequently reach the general circulation.

-A male, aged 60 years, was admitted to hospital on Jan. 27th. 1909, suffering from callous ulcer of 20 years' duration. It almost completely encircled the right leg in its lower half. The ulcer was foul, the fibula was in part bare, and the limb was ordenatous as far as the kneeinto the patient was suffering from profound anemia and toxemia. The vessels were much thickened, and the heart was weak and irregular. There was no albuminuria or glycosuria. On Feb. 2nd the leg was amputated at the seat of election by the above method of anæsthesia. 120 cubic centimetres of 0.5 per cent. novocaine were used; absolute anæsthesia was obtained; there was no evidence of shock, the pulse-rate before, and after amputation being. before and after amputation being 83. The after-history was uneventful; suppuration occurred, however, so stitches were removed and
the wound was allowed to heal by granulation. No necrosis of bone
occurred, and the wound was soundly healed by April 19th, on which
day the patient, having been provided with a knee-rest, left the
hospital day the pa hospital. CASE 2.—

hospital.

CASE 2.—A female, aged 45 years, was admitted to hospital on Jan. 26th, 1909, with moist gangrene of the third toe of the left foot. It had commenced in a slight injury sustained four months previously. On admission there was cellulitis extending on to the foot. Both legs were ordematous. There were no sensory changes nor vascular disease. The urine contained a trace of albunin; no sugar was found while the patient was in the hospital, though it was stated to have been present in the out-patient room. Amputation of the toe at the metatarsophalangeal joint was performed on Feb. 4th by the above method of aneathesia. 50 cubic centimetres of a 0.5 per cent. solution of novocaine was used. The operation was commenced ten minutes after infiltration; the patient felt the skin incision, although it did not evoke pain. Owing to the condition of the tissues the wound was left open. Vomiting occurred once 12 hours after the operation; apart from this owing to the condition of the tissues the wound was let open. Vomiting occurred once 12 hours after the operation; apart from this recovery was uneventful, and the patient was discharged on Feb. 22nd, the wound having completely healed. The incompleteness of the anæsthesia in this case confirms Professor Bier's observation that the method is uncertain when applied to the hand or the foot; it probably results from the difficulty in completely depleting these areas of bood.

CASE 3.—A male, aged 76 years, was admitted to hospital on Feb. 1st, 1899, for senile gangrene of the left foot, which had commenced a fortnight before. The patient had suffered from polyuria and wasting for two years, and had had a slight right-sided hemiplegia I2 months previously. On admission the first, third, and fourth toes of the left foot night before. The patient has suffered from polyuria and washing for two years, and had a slight right-sided hemiplegia 12 months previously. On admission the first, third, and fourth toes of the left foot were in a state of dry gangrene; pulsation could be felt in the popliteal and posterior tibial vessels of this side but not in the anterior tibial. The urine averaged 75 ounces daily and contained albumin and sugar. On a modified diet the daily excretion of sugar dropped from 1400 to 700 grains. In spite of rest, &c., the gangrenous process began to spread and the patient was having much pain, so on Feb. 6th circular amputation was performed at the lower third of the thigh, venues anæsthesia being used. The septic condition of the foot made it necessary to apply the Esmarch bandage entirely above the gangrenous area. 100 cubic centimetres of a 0.5 per cent. solution of novocaine were injected. The pulse rose from 96 to 122; the patient sweated and womited once. From its appearance some circulation was still present in the operation area, and the rise in the pulse-rate was apparently due to the fact that some novocaine had reached the general circulation. The tourniquet was therefore reapplied, and, as anesthesia was as yet imperfect, a further 60 cubic centimetres of the solution were injected. The patient now complained of much pain in his toes, so he was given chloroform inhalation (one drachm in all being used) for the skin incision. Consciousness rapidly returned, but there was no further rise of the Consciousness rapidly returned, but there was no further rise of the pulse-rate, and no evidence that he experienced pain during the division of nerves or bone. Unfortunately the patient's heart began to fail on Feb. 10th and he died on the 14th.

of nerves or bone. Unfortunately the patient's heart began to fail on Feb. 10th and he died on the 14th.

Necropsy.—The lungs were congested and ordematous. The heart was hypertrophied; the myocardium was unduly soft, and there were atheromatous patches on the mitral valve. The aorta was riddled with atheromatous patches, and all the larger and medium-sized vessels were rigid and calcified. The head of the pancreas was unduly hard. Microscopy showed fatty infiltration; the islands of Langerhans were scarce. The kidneys were moderately granular. The brain showed no gross lesion to account for the old hemiplegia, but the lumen of the left middle cerebral artery was much diminished. Examination of the amputation stump showed no attempt at repair. The artery was rigid and calcareous, and no clot was present above the ligature.

In this case the rigidity of the artery accounts for the difficulty experienced in emptying the operation area of blood. In the production of the pain there were probably two factors. Firstly, owing to the septic coudition of the foot, the Esmarch bandage had to be applied entirely above it; the result of this was venous congestion of the foot. Secondly, owing to the rigid condition of the vessels, more pressure than usual had to be applied to produce harmostasis.

CASE 4.—A male, aged 43 years, was admitted to hospital on Jan. 11th, 1909, for chronic synovitis of the right knee of two years' duration. The skiagram showed no disease of bone. On Feb. 15th the joint was explored by Mr. C. A. Ballance, venous anasthesia being used. 100 cubic centimetres of a 0.5 per cent. novocalne solution were injected into the internal saphenous vein, perfect ansethesia being obtained in five minutes. The synovial membrane of the subcrureal pouch, and that on either side of the patella, was found to be studded with tuberculous nodules (verified by the microscope). The diseased synovial membrane was therefore removed. On account of considerable oozing into the joint cavity the latter was drained for 48 be studded with tuberculous nodules (verified by the microscope). The diseased synovial membrane was therefore removed. On account of considerable oozing into the joint cavity the latter was drained for 48 hours. The pulse-rate at the beginning of the operation was 90. Two hours later it increased to 100 and became irregular, but had again dropped to 90 in 12 hours. In 48 hours the pulse, though regular, was weak. Subsequently some superficial suppuration occurred. The wound had healed by March 23rd, on which day the patient, having been provided with a leather splint, left the hospital.

CASE 5.—A male, aged 44 years, was admitted to hospital on Feb. 14th, 1909, with an ununited fracture of the tibia and the fibula. The patient had sustained a compound fracture is months previously.

Feb. 14th, 1909, with an ununited fracture of the tibia and the fibula. The patient had sustained a compound fracture six months previously; a portion of the tibia between three and four inches in length had necrosed and come away. The patient was an alcoholic subject; there was no arrempt at new bone formation; the foot was ordematous and paticul, and there was a large pressure sore on the heel. Amputation below the seat of election was performed on Feb. 20th, 1909, venous

angsthesis being used. 120 cubic centimetres of 0.5 per cent. novocaine

anæsthesia being used. 120 cubic centimetres of 0.5 per cent. novocaine solution were injected into the internal saphenous vein; the tourniquet caused some slight discomfort which rapidly disappeared as anæsthesia became established. There was no alteration in the pulse-rate during the operation, but in this case some cardiac irregularity appeared on the fourth day. The wound bealed per primam, the patient was provided with a knee-rest, and left the hospital on March 12th.

CASE 6.—A female, aged 39 years, was admitted to hospital on Feb. 6th, 1909, for diabetic gangrene of the left foot of six weeks duration. The foot was red, ordematous, and covered by numerous ulcers and bulke; some of the metatarso-phalangeal joints were disorganised and the corresponding metatarsal bones and phalanges were exposed. Before admission the foot had been treated with hot carbolic dressings; cellulitis had spread to the lower third of the leg, and the skin up to this level was red, ordematous, and covered with vesicles; the upper limit of the inflammation was sharply defined, and corresponded to the level of the dressing. The patient could move her toes, but sensation was impaired, and there was considerable pain. The vessels were thickened beyond her years, but pulsation could be felt in the anterior and posterior tibial arterics. The knee-jerks were absent; otherwise there were no symptoms of disease of the central nervous system. The urine, which averaged 50 onnees per diem, contained albumin and sugar (1800 grains daily). On standing it became dark green, and the distillate gave the carbolic acid tests. The patient was placed upon a modified diet; the foot was incised on several occasions under local anæsthesia and treated with baths and dry dressings. The cellulitis subsided, the general condition became much better, the carboluria rapidly obtained by the above method; no discomfort was experienced; the pulse-rate at the beginning of the operation was 140, at the end 120. (Previous to operation her pulse-rate varied between

Pulsation could be felt in the anterior but not in the posterior tibial artery. The patient had polyuria and the urine contained much albumin and sugar (average daily excretion 3000 grains). The temperature reached 101° F., the gangrenous process continued to spread, and the patient was rapidly going down-hill, so amputation at the lower third of the thigh was performed on March 25rd. Venous anæsthesia was used (in this case 200 cubic centimetres of a 0.25 per cent. solution of novocaine); the patient was highly nervous, so a prelliminary injection of a quarter of a grain of morphia was given. Owing to the condition of the tissues the Esmarch's bandage was applied entirely above the septic area; this produced pain in the foot, and chloroform inhalstion became necessary until indirect anæsthesia was established. The patient was perfectly conscious, however, for the division of the nerve trunks and bone, and experienced no discomfort at this period. The pulse-rate before operation was 88, at the end 90. Unfortunately, the heart began to fail two days later and the patient died on March 28th. March 28th.

March 28th.

Necropsy.—The heart was soft, large, and dilated (especially the right side) without much hypertrophy being present. The kidneys were large and pale. The amputation wound showed no attempt at

CASE 8.—A male, aged 58 years, was admitted to hospital for gangrene of the right foot, which started a month before admission. During the previous eight months he had been under treatment for diabetes in the out-patient department; he had also attended an eye hospital, where he was told he had "diabetic hæmorrhages in his disc." On admission was told he had "diabetic hæmorrhages in his disc." On admission there were redness and ordema extending on to the dorsum and the sole of the involved foot. There was practically no pain; pulsation could be felt in both anterior and posterior tibial arteries. There was no lesion of the heart, nor did his vessels appear to be thickened beyond his years. The knee-jerk on the right side was obtained with difficulty; on the left side it was absent. The urine, which averaged 65 ounces daily, contained albumin and sugar; the daily excretion of the latter was 1100 grains. With rest and a modified diet the cellulitis subsided and the daily excretion of sugar dropped to 90 grains. For early a week the patient continued to improve, but then the gangrenous process began to spread and he suffered much pain. On April 7th amputation was performed by venous anæsthesis, 150 cubic centimetres of 0.5 per cent. novocaine solution being used. The patient's nutrition and vascular system seemed so good that it was decided to amputate at the seat of election. Good anæsthesis was obtained, but he had a twinge of pain as the anterior tibial nerve was decided to amputate at the seat of election. Good ancethesis was obtained, but he had a twinge of pain as the anterior tibial nerve was divided. There were no alteration in the pulse-rate and no shock. Unfortunately, hemorrhage from the stump occurred on the sixth day. The wound was opened up and the bleeding posterior tibial artery was secured. There was no attempt at repair and the flaps had commenced to slough. The patient did not recover sufficiently to make re-amputation possible; he gradually sank and died three days later.

Necropsy. -The aorta showed patches of atheroma. The heart was

Necropsy.—The sorts showed patches of atheroms. The heart was slightly enlarged and the mitral and aortic valves showed early scierotic changes. The popliteal artery on the amputated side was practically normal; the posterior tiblal artery was calcareous and rigid. The kidneys were large and pale. The pancreas showed neither macroscopic nor microscopic changes.

CASE 9.—A female, aged 55 years, had been under private treatment for diabetic gangrene of her left foot for three months. On admission to hespital on July 3rd, 1909, the anterior part of this foot was foul and gangrenous. The general condition was good. The cardio-vascular system presented no gross changes. Pulsation could the felt in both the anterior and posterior tiblal arteries of the diseased side. The kneeligeks were present. There was polyuria, and the specimen contained much albumin. The daily excretion of sugar was 2420 grains; on a

modified diet this had dropped at the end of a fortnight to 1000 grains. The gangrene now began to spread along the inner aspect of the foot, and the patient was having much pain. Amputation through the lower third of the thigh was therefore performed on July 18th under venous anæsthesia. A preliminary injection of a quarter of a grain of morphia was given, as the bandage had to be applied entirely above the gangrenous area. The congestion of the foot resulting from the latter procedure caused considerable pain, and the spalse-rate rose from 92 to 104. A further injection of morphia was therefore given. Good anæsthesia was soon obtained, 150 cubic centimetres of a 0.5 per cent. solution of novocaine being used. The patient, however, suddenly lapsed into coma before the completion of the operation. She was infused with sodium bicarbonate, &c., but remained comatose until death, which occurred two days later.

Necropsy.—The kidneys were large and pale; the sorta was atheromatous. The pancreas and other organs showed no gross lesion.

COMMENTS.

If the technique be carefully carried out absolute anæsthesia will in most cases be readily obtained. Professor Bier reports two cases where analgesia only was present; this, however, was of such a character that the operation could be completed without resort to general narcosis. In our own cases the local anæsthesia has been perfect except in one case involving the toes only (Case 2). Probably the cause here was failure to empty the part of blood. In this instance, however, the analgesia was sufficient for the completion of the operation. In three cases in which the Esmarch bandage had to be applied above an infective focus, pain in the foot was evoked by the resulting venous congestion. Thus in Cases 3 and 7 a small amount of chloroform was necessary for the early stage of the operation. In Case 9 an injection In all these cases the pain passed off sthesia became established. When the of morphia sufficed. when "indirect" anæsthesia became established. Esmarch bandage can be applied to the whole of the distal portion of the limb it can be applied sufficiently tightly without causing discomfort, except perhaps in those cases where the arteries are calcareous and rigid. Failure of the upper bandage to secure hæmostasis (and as a result imperfect anæsthesia) may occur in patients whose arteries are rigid. The same difficulty may arise where the thick part of the thigh is the seat of operation; thus in one case we had to employ the ordinary tubular tourniquet, a proceeding associated with considerable discomfort.

The danger of toxic symptoms from novocaine will only arise at the moment when the upper bandage is loosened, or when perfect hæmostasis has not been obtained. In our own amputations the amount of novocaine gaining access to the general circulation has not been sufficient to alter the pulserate, except in the case of an old man (Case 3) whose arteries were extremely rigid. Obviously, toxic symptoms are less likely to occur in amputation cases (where the solution has free egress from the divided tissues) than in more limited operations. In the former cases drainage of the wound for 24 hours is advisable. Professor Bier has recorded one case in which toxic symptoms arose. 150 cubic centimetres of a 0.25 per cent. novocaine solution had been injected; 15 minutes after removal of the bandage the subject, a woman, aged 60 years, vomited, and her pulse became small and quick. She rapidly recovered, however, and had no further symptoms. In a good many of our cases some irregularity and increase in the rate of the pulse were noted on the second or the third day. This late and transitory disturbance of the cardiac system we have also seen in some cases where only 10-20 cubic centimetres of a 0.5 per cent. novocaine solution had been used for producing anæsthesia by perineural injection. Professor Bier has recommended that at the completion of the operation the upper bandage should be very gradually relaxed, thus preventing too rapid diffusion of the novocaine. He has also suggested that normal saline solution should be run through the veins in the isolated area. might be urged as an objection to this form of anæsthesia that the technique requires too much time. In a thin subject where the vein is readily found this should not take more than 15 minutes. In fat subjects, however, it is, for this reason, inferior to spinal anæsthesia for operations on the lower limb. In the case of the upper limb, when general anæsthesia is contraindicated, it seems to us to be a method of the greatest value.

For permission to publish these cases we beg to acknowledge our indebtedness to Mr. H. H. Clutton, Mr. W. H. Battle, Mr. C. A. Ballance, Mr. H. Betham Robinson, and Mr. E. M. Corner, under whose care the patients were admitted to hospital.

AN EPIDEMIC OF ENTERIC FEVER, PROBABLY DUE TO INFECTION BY A "CARRIER."

BY HENRY ROSCOE, M.R.C.S. Eng., L.R.C.P. LOND., D.P.H. VICT.,

SENIOR ASSISTANT MEDICAL OFFICER AT CHEDDLETON COUNTY ASYLUM, STAFFS

THERE is grave doubt whether it can ever be proved beyond all cavil that any case of enteric fever has been infected by a carrier, for the difficulties in the way of absolutely excluding every other possible source are practically insurmountable. We now know that, whether or no the bacillus typhosus ever actually spores, certain individuals do occur which have such special powers of resistance and survival for lengthened periods, that they are as dangerously long-lived as sporing bacilli; infection may therefore lurk in unsuspected places long after its possibility has been lost sight of. On the other hand, it is almost equally difficult to prove that a probable carrier has actually infected any given case; the destructive critic could find weaknesses in any such case yet reported or likely to be reported. The following account of a slight epidemic at Cheddleton Asylum, which commenced in September, 1908, and lasted until March, 1909, justifies, in my opinion, faith in the carrier theory as an explanation. Owing to specially favourable circumstances, exclusion of other sources is almost completely possible, whilst there was on the scene a carrier who was capable of causing the mischief.

The asylum, opened in 1899, originally contained 16 wards; eight additional wards were completed and opened in April, 1909. It was in one of these new wards, F 19, that the epidemic began. From first to last there were 12 cases, all females. Enteric fever was not diagnosed for a few days as there had been no case here for six years. During these few days the first three patients, Fa, Fb, and Fc, were not isolated, and one of them, Fa, who was nursed in the sick room F11, was in close contact with a working patient, Fd, who helped to remove slops, &c. Fa began to be ill on Sept. 26th, Fb and Fc on the 29th; Fd was attacked on Oct. 12th, Fe on Nov. 3rd, Ff on the 6th, Fg on the 15th, Fh on the 26th, Fi on the 27th, Fk on Jan. 12th, Fl on Feb. 3rd, and Fm on March 9th.

Since the last-mentioned date up to that of writing, Oct. 1st, there has been no case resembling enteric fever, although in several instances of slight fever a Widal test has been applied with negative results. A positive reaction had been obtained in all the 12 cases noted above, with the exception of that of Fi, who died on the tenth day of illness after perforation. Nine of the 12 cases occurred in ward F 19, the exceptions being Fd, Ff, and Fm. Fd has already been accounted for; F f was a refractory patient in ward F 14, who was dirty in habits and who required attention at night, this being supplied by a relief night nurse, somewhat inexperienced, who also attended to similar cases in F 19. Assuming for the moment that there was a carrier in F 19, and that she was a patient of dirty habits who required attention at night, the connexion is obvious. As regards F m, there is no really satisfactory explanation. She lived in ward F 15, which is in the same block as F 14, and, being at times refractory, was at such times sent for short periods to F 14, and was so sent on several occasions about the time when she became infected. It can only be suggested that she came in contact with some infective matter which had escaped sterilisation when the ward was disinfected after Ff sickened. As Fm was a restless patient, with wellknown propensities for picking up and hoarding rubbish, this is a possible, if not a convincing, explanation.

It should be mentioned that all cases were, as soon as diagnosed, removed to the asylum isolation hospital, and that thorough disinfection was carried out after each case occurred. The procedure was to wash floors, walls, fixtures, furniture, &c., with either chloros or formaldehyde solution, 1 per cent., according to the nature of the article to be disinfected, and to follow this up by spraying with formaldehyde solution, finishing up by aerial disinfection with gaseous formaldehyde, using a quantity of formalin calculated to give 0 :25 per cent. of HCOH in the air.

It is clear that infection commenced in ward F19, the inmates of which are mostly infirm old women, and which

was, ipse facto, less open to typhoid infection than any of the other female wards. The milk, food, and water-supply were the common supply of the rest of the asylum; nevertheless, samples of water from all the ward taps were submitted to Professor R. F. C. Leith of Birmingham University for examination, with negative results. No food, luxuries, or any other articles were brought into the asylum by the friends of Fa, Fb, and Fc within the month preceding the beginning of the epidemic. Infection by flies may be excluded, as the asylum is singularly free from them. Its situation is windy and exposed, the trees are not yet grown, and the soil is exceptionally quick-drying. In the day-rooms, dormitories, corridors, and subways it is often impossible, even in summer, to see a single fly; and during September, 1908, and the succeeding months there was no rise above the normal number.

The county medical officer made an exhaustive investigation, and came to the conclusion that infection by any of the above-mentioned sources might be excluded, but suggested that there might be a carrier in the infected ward, and advised that all patients and staff who had been in the ward since its opening should be subjected to the Widal test. This was done; on Feb. 8th Professor Leith reported that in every case but one the result was negative. The exception was M. B., an old woman, aged 75 years, her blood giving a positive reaction. In consequence of this report M. B. was thereafter looked upon as a possible source of infection, and was kept at the isolation hospital until her death on April 23rd. In the interim samples of her urine were sent to Professor Leith, but he found no typhoid bacilli therein. On post-mortem examination no trace of recent disease was found in the intestines. The mesenteric glands were normal with the exception of a few, which were almost cartilaginous in consistency; there were also evidences in the lungs and elsewhere of obsolescent tubercle. The spleen was exceptionally small, only weighing 76 grammes, and was quite normal. The gall-bladder was dissected out with due care and was found to contain two small black stones and a small amount of inspissated bile. The walls were contracted and thickened, but there was no naked-eye evidence of catarrh. The cause of death was senile decay, the aorta and the arteries and veins generally being markedly atheromatons. The gall-bladder and its contents were sent to Professor Leith, and on May 5th he reported: "The gall-stones did not show the presence of bacillus typhosus; but the gall-bladder, besides containing the bacillus coli and other germs, undoubtedly contained the bacillus typhosus. From the rich bacterial content of the gall-bladder we have isolated a bacillus which gives all the reactions of the bacillus typhosus, including agglutination in dilutions of 1 in 100 with a known anti-typhoid serum.
M.B. was an undoubted typhoid carrier."

As regards the known previous history of the patient, one of her daughters states that six years ago she had an "apoplectic fit," but that, after some weeks in bed, she showed no signs of paralysis on getting about again. This was her only illness so far as is known during the past 20 years. She was admitted to the asylum on April 17th, 1908, and transferred to F 19 on May 6th, remaining there until removed to the isolation hospital on Feb. 8th. She was, when admitted, in fair health considering her advanced age, her mental condition being one of senile dementia. She deteriorated steadily physically until her death. She was a very troublesome patient, restless and never still during the day-time, dirty in habits and always requiring attention at night.

During the anxious period that followed recognition of the fact that enteric fever had broken out all patients in the infected ward were, of course, kept continuously in bed and temperatures recorded. M. B.'s temperature was never at any time above normal. If, therefore, she contracted enteric fever in the asylum at some period prior to Feb. 8th, 1909, when her blood gave the Widal reaction, she must have been an apyretic case without a single symptom. The inherent probability is infinitely greater that she had suffered from a mild attack of the disease at some antecedent period, without its being recognised or treated. This point, however, though of great importance to the asylum, is immaterial to the larger issue. What is beyond all question is that this old woman of 75, who had had an attack of enteric fever at some period not less than 11 weeks before her death, was at death capable of unlimited infection. The bacillus typhosus was vigorous and well established in her gall-bladder, and

there is no reason to doubt that, had the patient survived, infectivity would have continued indefinitely.

It is highly probable that in a fair percentage of recovered cases of enteric fever the bacillus typhosus exists in the gall-bladder and is capable of more or less intermittent mischief for months or years to come. Has not the carrier been responsible for most or all of the mysterious epidemics or isolated cases which all know so well, and which have caused such labours of the parturient mountain of worry with the resultant ridiculous mousebirth of explanatory theory?

How, then, to deal with the problem of preventing infection? Shall the surgeon be called in to explore the gall-bladder after every case of enteric fever, and, with the aid of the bacteriologist, to determine whether infection persists? or shall the attempt be made to have the stools of all enteric patients sterilised for the remainder of their lives? The administration of intestinal disinfectants sine die is, of course, neither desirable nor effective, nor does one suggest that either of the other procedures is really practical politics. Perhaps some harmless yet efficient bactericide may yet be built up which may safely be injected into the gall-bladder in sufficient quantity, but the time is not yet.

THYROIDECTOMY AND A THEORY OF CANCER CAUSATION.

BY WILLIAM STUART-LOW, F.R.C.S. Eng., SURGEON CETTRAL LONDON THROAT, NOSE, AND KAR HOSPITAL, AND LECTURER ON RHINOLOGY AND OTOLOGY, MEDICAL GRADUATES COLLREE.

THERE is still much in the normal action, the physiology, of the thyroid gland that is hidden from us. It is certain, however, that sufficiently impaired function results in the tissues, so to speak, becoming water-logged with mucin-the establishment of myxœdema. I have never seen cancer and myxcedema at the same time in the same patient, and it is quite possible that the existence of excess of mucin in the tissues may act as an insurance against the origin of carcinoma and sarcoma. The antithesis of thyroid sluggishness and over-abundance of mucin in the system would be thyroid over-work, and consequent diminution in the normal quantity of tissue and surface mucin. This is the state of the system that I believe to have detected in malignant disease; and it constitutes in its earlier stages, in my opinion, the true precancerous condition-viz., hypomyxia, both of tissue and surface mucin, as enunciated in "Mucous Membranes, Normal and Abnormal, including Mucin and Malignancy" (Baillière, Tindall, and Cox), and "Mucin and Malignancy: Facts and Theories" (THE LANCET, Sept. 20th, 1902, p. 807). The smaller thyroid producing but little secretion is the common condition in over-fed people with much subcutaneous fat. When this thyroid inaction passes to an advanced degree atrophy occurs, with the result that myxcedema supervenes. It is, on the other hand, a remarkable fact and well recognised that in the bodies of those whose death has been due to wasting diseases, such as tuberculosis and carcinoma, the thyroid is found to be large, showing evidence of much secretion having been thrown into the system. This everaction may have gone on for months and have given rise to the great emaciation seen in these subjects. Another point, of which I have never been able to get or give a satisfactory explanation, is that there exists in most cases of carcinoma a quickening of the pulse. May this not be another evidence of increased thyroid action? The obvious rapidity with which wounds in the cancerous heal is very striking and indicates increased metabolism and tissue change, and may, perhaps, be explained by the increased functional activity of the thyroid.

For some time, after years of careful observation of many cases of carcinoma and sarooma in all stages, I have come to the conclusion, looking on the thyroid gland as the fly-wheel of body growth and metabolism, that this organ is very liable to over-work, that the body metabolism in this manner is liable to become over-driven, and that so the thyroid may be a causation factor in the origin and continuation of malignant disease. Holding these views, I have long had it in contemplation to perform more or less complete excision of the thyroid gland in inoperable carcinoma as the best means of eliminating or ameliorating a

disturbing factor in the diseased organism of the carcino-This having now been carried out in three instances the following are the facts about these cases.

CASE 1.—An elderly man, aged 63 years, went to the Central London Throat, Nose, and Ear Hospital because of difficulty and pain on swallowing and on account of a large swelling on the left side of the neck at the angle of the jaw. After careful examination by my colleagues the case was pronounced to be epithelioms of the base of the left side of the tongue and quite beyond operation. 14 days later Dr. W. F. Colclough of Sidmouth sent him to consult me privately. A large mass of hard glands was found below the left angle of the jaw, and a carcinomatous ulcer of the size of a penny very far back on the left part of the base of the tongue. This had already begun to spread on to the palato-glossal fold and to a small extent to the side of the adjacent floor of the mouth. There were well-marked induration and considerable pain shooting into the ear and upwards and backwards to the occipital region. The history was that only during the last month had he had pain to speak of, and that only on seeing Dr. Colclough had he been told of the grave nature of the malady. I doubted the likelihood of getting away all the growth, but the patient pressed me so hard to do something because of the pain on attempting to eat and at night that I consented. On Dec. 2nd, 1908, the entire left half of the tongue was removed right back to the hyoid bone, together with the palato-glossal pillar and adjacent affected part of the floor of the mouth; and afterwards the thermo-cautery was freely applied. Laryngotomy was first performed and the cheek split to give free access; the mass of cervical glands was also excised. The patient stood the operation well and was able to return to Devonshire on the eighth day. For six weeks he did very well and was able to eat and speak wonderfully, but the following week the neck began to swell, and Dr. Colclough, after trying cinnamate of soda injections, sent him up to me again with recurrence of the disease, characterising him, quite justifiably, as "doomed."

An extensive recurrence was found—a mass of hard glands in the neck at the original seat of operation, which was already breaking down in the centre and discharging blood and pus. The left side of the floor of the mouth bulging up was full of an ulcerated mass of growth, which extended backwards to the same side of the pharynx and base of the remaining half of the tongue. He had a considerable degree of dyspnœa; consequently it was decided to perform a low tracheotomy at once. This was done next morning, but a complete excision of the thyroid gland was first performed. Chloroform being administered, the entire thyroid was exposed by means of a semilunar collar incision. gland was firmly bound down to the adjacent structures as if there had been an inflammatory condition causing adhesions; it was very vascular, necessitating the tying of many vessels, the whole thyroid, however, being removed in one piece. Tracheotomy was then per-formed, and the patient, having stood this operation removed in one piece. well with no evidence of shock, was back in bed in an hour from the commencement of the operation. The recovery was uninterrupted, the patient being up on the second day; the wound healed by first intention, and he was out walking in the sun on the seventh day. On the twelfth day the mass in the neck had almost ceased to discharge, was considerably smaller, and not at all painful; the induration had also lessened. The patient was able to swallow and talk much better, and could open the mouth further and without pain, there being also diminution of the swelling and hardness in the mouth and pharynx. The profuse flow of saliva from the mouth was now much reduced; the pulse and temperatere became normal, the pulse being 68 per minute. (This varied from 76 to 83 before the excision.) Altogether the patient seemed better after the complete removal of the thyroid, being much brighter in himself, feeling more comfortable in every way, and sleeping longer at a time. The only other treatment consisted in the administration of macin, and as far as possible an anti-hypomyxiatous diet. He took three ounces of the elixoid mucin a day, by sipping, as it was most soothing and moistening to the tongue and threat

The question was-Would this patient become myxcedemeatous, and if not, why not? If myxœdema developed at all it should be late in appearing, because the theory is that mucin being so deficient in the carcinomatous subject, even

after complete removal of the thyroid, it would be long in accumulating to such an extent in the tissues as to show itself in the usual myxcedematous manner. The idea that the thyroid gland had been overworking was borne out by the result of the pathological examination. The following is the report of Dr. George Eastes: "The thyroid tissue shows no encapsulated growth, and to the naked eye nothing but general hypertrophy is suggested. Microscopically some of the gland spaces are dilated, but there is no gross lesion anywhere. The case is one of diffuse parenchymatous hypertrophy." Dr. Wyatt Wingrave's report also bears this out: "Specimen of thyroid gland, received Feb. 14th, 1909, from Mr. Stuart-Low. There is but little variation from the normal thyroid. The most characteristic features are: 1. Increase in the interlobular connective tissues, which is also marked in the acini. 2. Congestion of the acini, which are on the whole somewhat smaller than normal. 3. Diminished staining action of the colloid substances. 4. Intra-acinous cells were normal.

The excision of the entire thyroid gland was performed on Feb. 14th, 1909, and the patient lived until June 22nd, 1909, when he died from septic pneumonia. During the four months he developed no symptoms of myxcedema. He was singularly free from pain, and the growth in the throat, mouth, and neck did not increase to any appreciable extent, but ultimately softened and broke down, the discharges during this process giving rise to the septic pneumonia. Another remarkable point about the case was the increase in weight—he gained 1 pound per week for two months after the excision of the thyroid.

Although certain that in this case the pain had been relieved (the patient being emphatic concerning this) and that the rapid increase of the growth had been arrested, I was disappointed with the result, and in no other case was the operation again undertaken until May 9th, 1909.

CASE 2.—The second case was that of a man, aged 45 years, whom I showed at the last meeting of the Laryngological Section of the Royal Society of Medicine on May 7th, 1909, as an inoperable case of epithelioma of the larynx. The man was a porter in the General Post Office, who came to the clinic at the Central London Throat, Nose, and Ear Hospital complaining of hoarseness and difficulty of swallowing of two months' duration. He gave a history of repeated attacks of influenza, but not of syphilis. A large, grey, mushroom-like mass was seen covering over and projecting into the larynx. About one-third of this mass was removed with forceps; this gave him considerable relief. Dr. Wyatt Wingrave reported that it was certainly a very rapidly growing epithelioma—"one of the most virulent that he had ever seen." In the discussion which followed at the he had ever seen." In the discussion which followed at the sectional meeting Mr. H. Tilley said that he thought the growth was certainly of a malignant nature and far too extensive to be operated upon. He also emphasised the presence of many enlarged glands in the neck.

On May 10th, 1909, under local anæsthesia (1 per cent. cocaine) a collar incision was made over the thyroid, the isthmus was divided, the left lobe isolated, and all the vessels proceeding to and from this ligatured. Suddenly the larynx became obstructed, probably from the large growth hanging over its entrance having become fixed in the passage. The patient very rapidly became cyanosed and respiration ceased. It was urgently necessary to perform trachectomy, when recovery quickly took place. This accident proved the wisdom of having used local anæsthesia as against general anæsthesia in the particular case. It was now found impossible to remove the thyroid without greatly prolonging the operation, and it was thought best to tie the superior thyroid of the right lobe, and trust to this and efficient ligation of the left lobe to minimise the thyroid function. The large wound was partially closed and firmly packed with gauze. This patient made an excellent and uninterrupted recovery, leaving the hospital in a fortnight; the left lobe of the thyroid, all the vessels of which had been ligatured, sloughed, and came away in the dressings with the ligatures.

It is now five months since the operation was undertaken, and the case has been watched very attentively. Before this operation the patient was rapidly getting worse and losing weight, but since then he has been putting on weight, having gained 1 stone 1 pound. He is now swallowing better, and the growth in the larynx and pharynx has diminished very much in size. There has been no pain,

and the patient is much stronger and expresses himself as feeling better in every way since being operated upon.

This is the first case in which ligation, as distinguished from excision, has been practised and trusted to for the partial ablation of the thyroid. Judging from the results in this instance, the plan would certainly seem to answer well. Ligation is a more rapid process than excision, and the thyroid in these cancerous subjects is often enlarged, very vascular, and very adherent to surrounding structures—therefore often most tedious and troublesome to isolate.

CASE 3.—The third case was that of a man, a painter by trade, aged 58 years, who came to the clinic at the Central London Throat, Nose, and Ear Hospital on May 22nd, 1908, complaining of pain in the tongue and neck, and of a swelling on the neck of six weeks' duration. There was an ulcer of the size of a shilling on the right side of the tongue. was excavated and indurated, and had the characteristic stony hardness around and towards the base of the tongue. The induration extended on to the palate and under the sterno-mastoid near the angle of the jaw. No doubt could be entertained as to the primary ulceration being epitheliomatous, or that the enlarged glands were a secondary extension from the tongue. The pathological report supported the clinical diagnosis, and it being considered futile to try to eradicate the growth thyroidectomy was decided upon. Complete hemi-thyroidectomy was performed on June 3rd, 1909, the left half of the thyroid, including half of the isthmus, being removed; it was found very vascular and adherent to the surrounding structures. The patient was in the hospital for a week after the operation, and during this time suffered no pain in the tongue or neck. For some time before the operation the pain in the neck, shooting from the tongue to the enlarged glands and up to the side of the head, had been so severe as to keep him awake, and necessitated his having hypnotics every night. He is now an out-patient and for some weeks returned to his work as a painter. The ulcer on the side of the tongue healed, the induration became much less, and the glandular swelling softer.

Case 4.—The fourth case was that of a man, aged 70 years, with a large excavated ulcer on the outer wall of the left side of the naso-pharynx and a mass of hard glands under the sterno-mastoid. He was in a very low and weak state when he first came to the hospital, and altogether a very bad subject for any operative procedure. He was rapidly losing weight and complained of great pain in the throat and neck. Under local anæsthesia, on June 16th, 1909, the thyroid vessels were ligatured on both sides. He recovered well from the operation, lost all his pain, and the glands lessened in size and softened somewhat. He was able to leave the hospital for his own home, which was a very poor one, on the tenth day. He lingered on for six weeks, and did not suffer much pain even near the end.

CASE 5.—The fifth case was that of a man, aged 65 years, with epithelioma of the soft palate, and some secondary glands on both sides of the neck. On July 10th hemithyroidectomy was performed under local anæsthesia. He is still under observation and has gained 6 pounds in weight. His general condition is good and the glands have become smaller and softer. He is attending regularly as an outpatient. A very interesting, instructive, and important change took place in the hard mass of glands on the right side of the neck in this patient, commencing soon after the operation on the thyroid-viz., gradual and progressive softening. This went steadily on until there was great tension of the superficial surrounding tissues, and it was decided to incise the swelling and anticipate pointing and ultimate bursting of the enlargement. On freely opening it a large quantity of glairy mucoid fluid was discharged, which, on pathological examination by Dr. Wyatt Wingrave was found to consist chiefly of mucin. The inference, therefore, may be taken to be that the removal of the thyroid had induced a myxomatous degeneration in the mass of cancerous glands. Since this incision the mass of secondary growth in the glands has slowly diminished, and much discharge has taken place ever since, containing pieces of broken-down tissue which have sloughed away. On inserting the finger a cavity can be felt where the mass of hard glands was.

There seems no doubt that partial removal of the thyroid has an influence on these growths. It seems to have a deterrent effect on the rate of growth of the primary tumour; the secondary glands, too, seem to be favourably affected, as

in these cases there was a softening change in the glands, and they were much less painful. In all cases the pain was very quickly relieved. The patients, instead of losing weight, as they were doing before the operation, put on weight. Another thing noted in all these cases was a distinct slowing of the rate of the pulse. The second, third, and fifth cases were operated upon at a much earlier date than the first and fourth, and it would appear to be best to intervene as early as possible, not waiting until the patient is too low and weak. I have put these cases on record as, so far as I can find, the treatment is new and seems warranted by the results.

Harley-street, W.

A FATAL CASE OF ENDOCARDITIS OCCUR-RING DURING SCARLET FEVER,

WITH A NOTE ON THE BACTERIOLOGY OF SCARLET FEVER AND ACUTE RHEUMATISM.

BY J. M. CLEMENTS, M.D. R.U.I., D.P.H.,
MEDICAL OFFICER OF HEALTH. BATLEY.

THE notes of this case are of interest for the following reasons: (a) The rarity with which endocarditis occurs as a fatal complication of scarlet fever; (b) the presence of a streptococcus in the diseased endocardium; (c) the isolation of a similar streptococcus from the synovial fluid of a mild case of scarlatinal rheumatism; and (d) the possible relations of this organism to scarlet fever, endocarditis, and acute rheumatism.

Clinical history.—The patient, a boy, aged five years, was admitted to hospital with a mild attack of scarlet There was no history of previous illnesses, and fever. the note made on admission states that the heart was then normal. The acute stage of the scarlet fever then normal. The acute stage of the scarlet fever soon passed off, the temperature being normal on the sixth day. On the eighth day of illness there was a slight rise of temperature, and from this to the eighteenth day the temperature varied between 98° and 100° F. The pulse-rate during the same period was accelerated, ranging from 100 to 148. This departure from normal caused some anxiety, especially as none of the usual complications, which were looked for daily, could be detected. A trace of albumin appeared in the urine from the thirteenth to the sixteenth day; it was only a faint trace, no blood was present, and it was not regarded as the cause of the rise in temperature. In the fourth week the temperature settled to normal and the patient was allowed to get out of bed. The pulse, however, still kept rapid, being usually over 100, and was frequently 130 or 140. At this time the boy was examined daily, and particular attention was directed to the heart and lungs, but with negative results. During the period from the fourth to the tenth week he was kept in the open air most of the day and a liberal diet with tonics was given. He did not make progress, but remained thin and anæmic, and did not enter into the games of the other patients. On the eightieth day definite signs of cardiac complications were observed for the first time. A note made on this day states that "the heart is dilated and there is a loud bruit audible all over the chest, transverse dulness half an inch to the right of the sternum and one inch outside the nipple line." Three days later (eighty-third day) the wrist and carpal joints of the right hand were swollen, and the patient complained of pain in this hand; there was no elevation of temperature at this time, as is usual with a swollen joint in scarlet fever. The degree of cardiac dilata-tion steadily increased; restlessness, dyspnœa, retching, and vomiting were prominent symptoms; and death occurred on the hundredth day.

Note made at the post-mortem examination.—"The liver and spleen are congested, but beyond this all the organs, except the heart, appear to be healthy. No infarctions were found. All the chambers of the heart are dilated, and all the valves are affected with vegetative endocarditis. Vegetations are present on every cusp of the aortic, mitral, tricuspid, and pulmonary valves; they are small, of the warty type, are confined to the edges of the valves, and do not extend to the mural endocardium. There is no tendency to ulceration, and there are no fungating masses such as are sometimes seen in malignant endocarditis. The vegetations appear to be quite recent and there is no thickening of the valves."

Smear preparations, made from the vegetations and stained, showed coccal organisms in groups and pairs among leucocytes and débris. Agar and blood-serum tubes inoculated with the vegetations and incubated gave a pure culture of a streptococcus, to the cultural characters of which I shall refer later, but before doing so I would draw attention to the following points as noteworthy in the clinical history. 1. The type of scarlet fever was very mild. 2. The occurrence of joint trouble for the first time so late as the eighty-third day. The usual time for "rheumatism appear in scarlet fever is during the second or third week of the disease. 3. The endocarditis probably commenced in the second week of scarlet fever, but was not detected until the eightieth day. The possibility of its existence was considered and the heart was carefully examined on many occasions, but no definite evidence of a lesion was discovered until the day stated. 4. Death was directly due to valvular endocarditis, a very uncommon cause of death in scarlet fever. While it is very rare to find this lesion post mortem in scarlet fever, there are clinical signs that it occurs in a small proportion, probably not more than 0.5 per cent. of the cases. In septic and fatal cases of the disease the heart is often seriously affected, but the damage is mainly done to the muscle wall, the muscle parenchyma and interstitial tissues suffering, rather than the endocardium. When the endocardium is attacked it is almost invariably the mitral valve that is affected, and there may be little or no clinical signs of a lesion. The true significance of a murmur appearing in the mitral area during an attack of scarlet fever or any of the infectious diseases, is often difficult to appreciate. It may indicate temporary weakness of the myocardium and papillary muscles, or it may be due to organic changes in the mitral valve. The following statement briefly summarises my experience of this condition in scarlet fever. onset of scarlet fever it is not uncommon to find a blowing murmur in the mitral area, systolic in time and well conducted towards the axilla, accompanied, perhaps, by a slight degree of dilatation, but as the acute stage of the disease passes off this murmur disappears, the heart returns to its normal size, and the patient leaves hospital with a sound heart. If, however, a murmur appears at a later stage of the disease, and especially if accompanied by a rise of temperature and accelerated pulse, not due to glandular swelling or other easily recognised complication, the probability that it is due to endocarditis of the mitral valve is very strong. A systolic mitral murmur appearing during an attack of scarlatinal rheumatism is in the large majority of cases due to endocarditis and will be permanent.

Basteriology.—The streptococcus obtained in pure culture from the diseased valves has the following characters. It occurs in fluid media in short chains of two to six, frequently in pairs and small clumps. It is, therefore, of the streptococcus brevis type. It is non-motile and Gram-positive. It does not grow on gelatine at 20°C., but grows well on agar and blood serum at 37° C. It does not produce acid nor clot in milk. When tested for acid production in Lemco broth containing 1 per cent. of the following sugars-glucose, maltose, galactose, levulose, lactose, saccharose, raffinose, mannite, salicin, and inulin-it is found to produce acid in three-viz., maltose, levulose, and saccharose. The serum of patients suffering from scarlet fever does not agglutinate it, nor does the serum of patients suffering from scarlatinal rheumatism. The blood serums of three scarlet fever cases were tested for the presence of opsonins. The indices were 0.94, 1.1, and 1.68 respectively. It is noteworthy that the case whose index was 1.68 was suffering at the time from rhoumalism.

At first I did not consider there was any causal relation between this streptococcus and the diseased endocardium. I had frequently isolated streptococci from the commoner complications of scarlet fever and from the circulating blood in septic cases (collecting the blood direct from the vein in the arm into a sterile glass syringe), and I had come to regard their presence as due to a secondary or terminal infection. But about this time I drew off some synovial fluid from the wrist-joint of a case of scarlatinal rheumatism, taking the same precautions to avoid skin contamination as in blood cultures, and after incubating it on agar and blood serum I obtained a pure culture of a streptococcus which gave the same sugar reactions and appeared to be identical in every way with the strain of coccus isolated from the diseased valves. This result

appeared to me to open up the question of the relation of this streptococcus to scarlet fever, endocarditis, and acute rheumatism. The relationship of streptococci to these diseases is a very wide and difficult problem, and I do not propose to discuss it here, but will conclude this note by referring briefly to the chief views that at present hold the field.

Scarlet fever.-Streptococci have for many years been regarded as playing an important part in the cause of this disease and its complications. This view is based mainly on the constancy with which streptococci can be isolated from the inflamed fauces and commoner complications. They are present in the breaking-down glands, in the pus from suppurating mastoids, in the heart, lung, and kidney complications, and not infrequently in the circulating blood of septic cases. The following criticism may be offered to the view that scarlet fever is due to a specific streptococcus as stated by Klein and others. No constant type of strepto-coccus can be isolated from the inflamed throat or the various complications of the disease. The application of Gordon's tests shows that a variety of streptococci can be isolated not only from the inflamed fauces, but even from the same complication. The streptococci isolated, even from septic and fatal cases, have a low degree of virulence when injected into animals and do not produce any condition resembling scarlet fever. It has been suggested that scarlet fever is not caused by one particular strain of streptococcus, but is capable of being produced by a variety of streptococci, and in support of this view are brought forward those so-called cases of scarlet fever following burns, surgical operations, and parturition, where no evidence of exposure to the infection of scarlet fever can be found. The absence of a constant type of streptococcus as tested by Gordon's methods would also lend support to this view. Against this view we have the clinical evidence that scarlet fever always breeds true; it does not lead a double life, appearing at one time with all the symptoms as we know them well marked, and at another time as some other disease or in some questionable form. For the present we must be content to regard the streptococcal origin of scarlet fever as not proved, and in this connexion it may be well to remember that, prior to the discovery of the Klebs-Löffler bacillus, streptococci were regarded as the specific cause of diphtheria.

Endocarditis and acute rheumatism.—The relation of streptococci to these two conditions may be considered together, endocarditis being a prominent, if not the essential, lesion in the symptom-complex known as acute rheumatism. Many investigators have from time to time described organisms they have found in the blood and diseased tissues of acute rheumatism, and during the last eight or ten years attention has been concentrated on the presence of a short streptococcus or diplococcus in the blood of this disease. This organism has been isolated by several observers, and notably by Poynton and Paine in this country, who have succeeded in isolating it from over 30 cases of acute rheumatism, and have demonstrated its presence in the blood, joint fluid, rheumatic nodules, and elsewhere during life, and in the heart's blood, pericardium, endocardial vegetations, and elsewhere after death. They have also shown that intravenous injection of cultures of this organism into rabbits produces all the cardinal lesions of acute rheumatism. Their observations and experimental results have been confirmed by Beaton, Ainley Walker, and Beattie. On the other hand, other bacteriologists, such as Horder, Andrewes, and Bulloch, have consistently failed to isolate cocci or other organisms from the blood of cases of acute rheumatism during life. They also state that only in a few cases have they obtained cocci from the lesions after death. failure of some of these observers to isolate organisms from the blood cannot be attributed to their methods of blood examination. Horder has shown that by using the same methods in cases of ulcerative endocarditis he has obtained positive results in over 90 per cent. of the cases examined. In some of the latter cases Pfeiffer's bacillus was isolated from the blood, a delicate organism that is grown only with difficulty. It would therefore appear that his methods of blood examination succeed if micro-organisms are present.

The explanation of the discordant results of these two schools may perhaps lie (1) in the difference of the technique employed; from the accounts given by some of the observers it would appear that sufficient care was not taken in obtaining

the blood to avoid skin contamination; (2) the results may be partly due to a failure to distinguish between cases of ulcerative endocarditis and acute rheumatism. It is now well recognised that in malignant endocarditis micro-organisms can practically always be obtained from the blood and that streptococci and pneumococci are those most frequently found. Moreover, the clinical distinction between these two diseases may be sometimes extremely difficult, and it is possible that in some of the cases where positive results have been obtained the disease was not acute rheumatism, but was malignant endocarditis.

Batley.

A CASE OF DUODENAL FISTULA CURED BY OPERATION.

BY R. LAWFORD KNAGGS, M.C. CANTAB., SURGEON TO THE LEEDS GENERAL INFIRMARY.

THE case of duodenal fistula reported below may advantageously be contrasted with two others recorded by Dr. Albert Ashton Berg of New York. One of Dr. Berg's cases resulted from a cholecysto-duodenostomy for obstructive jaundice due to cancer of the pancreas, and the other followed an operation for perforated duodenal ulcer complicated by a localised peritoneal abscess. The method of treatment finally adopted in both cases was the performance of a gastro-jejunostomy and occlusion of the pylorus. The latter was produced by an encircling band, in one case of large-sized ligature silk, and in the other of tape only tied sufficiently tight to occlude the lumen but not to constrict the tissues. This plan does not seem to be free from the danger of ulceration of the tissues by the ligature, for it is impossible for occlusion to be produced by it without a certain degree of pressure. And, in fact, this occurred in the one case from which any conclusion could be drawn, but not to such an extent as to lead to disaster. Still, Dr. Berg believes the encircling ligature to be the best plan, and points out very truly that the infolding of the pylorus by superimposed rows of Lembert sutures, though possibly easy when the tissues are normal, is quite a different thing when the peritoneal surfaces of the viscera have become brittle and friable and fixed in inflammatory exudate. In the writer's case the pylorus was occluded by infolding in the manner suggested by Kelling (vide Berg's paper), except that no attempt was made to make a kink by suturing the end of the stomach to the first and second parts of the duodenum. That was impracticable owing to the thickness and firmness of the roll which was formed by the infolding, and further it appeared, and subsequently was proved, to be unnecessary.

As in other hollow viscers not completely invested by peritoneum a perforation of the duodenum may be either intra- or extra-peritoneal. The clinical features of the two forms are very different. As the following case shows, those of the extra-peritoneal form may be very misleading and a diagnosis may be impossible before the escape of duodenal contents puts the matter beyond doubt. On the other hand, intra-peritoneal rupture is attended by such marked and definite symptoms that it is usually recognised promptly and without difficulty. The treatment of a fistula resulting from extra-peritoneal perforation-if it refuses to close of its own accord—presents no particular difficulty if it is dealt with upon Kelling's plan, because the parts are healthy and aseptic; but it is only necessary to study Dr. Berg's cases to realise how hard it is to close a fistula when the parts are inflamed and softened and the field of operation is septic, conditions which are almost certain to be present when it is the result of an intraperitoneal opening.

A girl, aged 17 years, was admitted to the Leeds General Infirmary on Oct. 27th, 1906. Three months before her admission, under Dr. A. G. Barrs, she began to have attacks of sickness and diarrhea and passed a little blood. The sickness came on after taking food and she would usually vomit once a day, but occasionally she would go for six or seven days without doing so. She also had pain which came on a quarter of an hour after a meal, lasted about an hour, and went away gradually. This condition persisted till the week before admission when she became worse. She had lost flesh.

On admission, nothing abnormal was found on examination of the abdomen and nothing definitely wrong in the chest, though a slight taint in the family history, nocturnal perspirations, and a rather rapid pulse suggested the possibility of tubercle. The urine was normal. At first the pain and sickness disappeared, though the patient was put upon ordinary diet, but about Nov. 7th she complained of pain in the right hypochondriac region, and the temperature rose and gradually assumed an intermittent type. On Dec. 12th a mass was noticed in the right loin, and the right knee was partially flexed and drawn up. On the 15th there was exquisite tenderness at the bottom of the right side of the chest. On Jan. 9th, 1907, under anæsthesia the swelling on the right side of the abdomen was hard and could be felt to disappear under cover of the ribs. It was largest just before it did so. Its boundaries were vague.

On Jan. 14th the patient was transferred to the surgical side where the condition was regarded as a subscute suppuration under the psoas sheath, producing flexion of the hip and lordosis. On Jan. 23rd an incision was made in the right loin through muscles that were very firm from inflammatory infiltration. An abscess was opened by manipulation with the finger through an indurated mass, and about an ounce of pus escaped and a drainage tube was inserted. On March 6th, drainage not being satisfactory, the resulting sinus was opened up, and owing to the disappearance of the induration a considerable cavity could be explored. It was still regarded as situated under the psoas fascia. On March 25th a portion of orange pulp was noticed on the dressings, and it was then realised that the curious odour of the discharge, which had been noticed for several days, was due to gastric fluids. There was no trace of bile or of fæces, but charcoal made its appearance on the dressings four hours after it had been taken. The patient remained an in-patient till April 16th, when the wound had contracted to the drainagetube track, but there was still a considerable discharge having the peculiar odour just referred to, and in which evidence of fluid food was frequently observed. She was now sent home

in the hope that the communication that existed with the

stomach or duodenum would gradually close.

The patient was readmitted on June 13th. No alteration in the amount or character of the discharge from the sinus had taken place, and whenever charcoal was swallowed some of it came away from the sinus in from two to five hours. Occasionally bubbles of gas escaped and the patient stated that a "rush" of discharge would occur when she was actually masticating her food. On July 3rd the abdomen was opened. Considerable evidence of past inflammation was found in the neighbourhood of the duodenum. adhesions which existed between the under surface of the liver, the duodenum, the pylorus, and the transverse mesocolon were numerous but not tough. Their separation before the duodenum could be examined caused some trouble. only trace of ulcer that could be detected was at the pylorus on the posterior surface. The finger pressing upon the anterior wall felt to impinge upon a depression as big as a threepenny-piece. This part of the pylorus was moveable to a certain extent. The stomach was quite healthy. A posterior gastro-enterostomy was performed, and then the pylorus was infolded by two rows of Lembert sutures parallel to its long axis, about 1½ inches long—one over the other. In this way the pyloric end of the stomach was converted into a solid roll a little thicker than the thumb. After the operation the sour odour at once disappeared from the discharge and no more particles of food were ever seen. The next day bile, which had never escaped before, was mixed with the discharge and persisted for about a week, gradually diminishing. The patient left the hospital on August 20th, 1907, when the discharge from the lumbar sinus had diminished considerably. The charcoal test was now always negative. A small sinus persisted for a long time, but had finally closed in April, 1909. Her general condition after the abscess eavity was thoroughly drained was always satisfactory and for the last year or more she has been the picture of health.

Leeds.

WEST LONDON MEDICO-CHIRURGICAL SOCIETY.— On Oct. 8th the winter session of this society was opened by the presidential address delivered by Dr. Neville T. Wood entitled "The Selection of Patients for Spa Treatment."

Medical Societies.

ROYAL SOCIETY OF MEDICINE.

CLINICAL SECTION.

Exhibition of Cases and Specimens.—Pneumonia with considerable Displacement of the Heart simulating Pleural Effusion.—Caroinoma of the Breast.

A MEETING of this section was held on Oct. 8th. Mr. A. PEARCE GOULD being in the chair.

Dr. J. L. Bunch presented a case of Mycosis Fungoides in a man, aged 50 years, who noticed last October some scaly patches on his limbs which were itchy and irritable. These patches increased in size and looked like eczema, except that they were very sharply defined. The whole of the trunk and limbs became gradually involved in a diffuse superficial infiltration, the pruritus increased, and softish granulomatous tumours made their appearance. The largest was of typical fungating, mushroom-like appearance. The condition had improved under the following methods of treatment—an injection of a preparation akin to soamin. light treatment, and X rays.

Dr. H. D. ROLLESTON exhibited a case of Pigmentation of the Mouth in Pernicious Anæmia in a man, aged 25 years, who was admitted to hospital on July 19th, 1909 for diarrhœa, anæmia, and enlargement of the liver and spleen. There was marked freckling of the lower half of the face, especially around the mouth. The lower lip presented inky pigmentation along the line of contact towards the angles of the mouth. On the oral surface of the right cheek there were one large and four small pigmented patches, and on the mucosa of the left cheek there were two similar pigmented patches. Inquiry showed that the patient had not taken arsenic before admission. Dr. Rolleston said that that supported Dr. Hale White's contention that oral pigmentation occurred in pernicious anæmia independently of arsenical treatment. The patient had greatly improved since he was put on arsenic.—Dr. F. PARKES WEBER said that the pigmentation made him think that the case might be one of an

Mr. Albert Carless showed a man from whom he had removed both the upper maxillæ for so-called Fibro-cystic Disease or Epithelial Odontome. Mr. Carless was congratulated on the successful and satisfactory issue of his operative procedure, and Mr. PEARCE GOULD recalled the circumstances of a similar case in which both maxillæ had been taken away for carcinomatous disease.

incomplete form of xeroderma pigmentosum.

Mr. JAMES SHEBREN showed a Meckel's Diverticulum containing calculi removed at an operation on a man aged 38 years. The condition had produced symptoms of abdominal colic and the patient was said to have passed gall-stones in his motions. When admitted to the medical side of the hospital with a history of a sudden onset of pain in the right iliac fossa the pain was described as "grinding" in character, and was accompanied by vomiting. Mr. Sherren saw the patient shortly after another attack and advised operation. On May 16th he opened the abdomen in the right iliac region. On examination he at once felt a bladder full of stones. On bringing it outside the abdomen its nature was at once evident. The diverticulum sprang from the antimesenteric border of the ileum, at its commencement being the same size as the ileum from which it sprang, dilating at its free extremity. The termination of the superior mesenteric artery ran in a fold of peritoneum along its anterior surface. It was quite free from adhesions. The specimen measured in the recent state four inches in length and was partially closed an inch from its attached end by a valvular fold of mucous membrane. Below this point it was filled with irregular brownish calculi which were very brittle. Analysis showed them to be composed of cholesterin, bile pigments, and calcium oxalate.

Dr. E. I. Spriggs showed a case of Infective Rheumatoid Arthritis with Enlargement of Glands and Spleen. The patient was a male, aged 16 years, a farm labourer. The trouble

and he was able to continue his work. On admission to hospital four weeks back the lad looked ill; his pulse ranged between 92 and 104, and his temperature rose to 99 5° F the evening. The interphalangeal joints, both distal and proximal, of the fingers and thumbs were red and enlarged, but the redness had now disappeared. The elbows, wrists, knees, and ankles were uniformly enlarged. The lymphatic glands were enlarged, soft, and discrete in the axillæ; the epitrochlear gland was about the size of a hazel-nut on each side; the glands in the groins were enlarged, as also some placed deeply above the clavicles. spleen extended about an inch below the left costal margin.-Dr. A. E. GARROD referred to the cases described as Still's disease, and said that similar cases did occur but more rarely in adult life, the difference in the clinical picture affording examples of the influence of age on a type of disease. Dr. ROLLESTON had seen a case at Cambridge in an adult similar to the case of Dr. Spriggs before Dr. Still had brought forward his cases.—Sir DYCE DUCKWORTH said that those cases of Dr. Still were possibly a blend of struma with the so-called arthritic or rheumatic habit of body.

Dr. G. A. SUTHERLAND showed a case of Flexor Spasm in a girl, aged five years. In June last the left hand was noticed to be held in a cramped position and not used. Two days later the child had a sort of fit, becoming faint and of a dusky colour, but did not lose consciousness. There was found on examination to be flexion of the fingers of the left hand into the palm. The ring and middle fingers were chiefly affected; the others could be easily extended and even hyper-extended by passive movement. If one straightened out forcibly these two fingers the wrist at once became strongly flexed; if the fingers and wrist were straightened the elbow became flexed. The hand was usually deviated to the ulnar side. The grasp of the left hand was good. There was no alteration in the reflexes or electrical reaction. The condition had persisted unchanged. contraction was not absent during sleep nor under an

anæsthetic. Sir DYCE DUCKWORTH exhibited photographs of a case of

Gout, with large Tophaceous Deposits, in a Mahomedan. The notes of the case had been furnished to him by Captain H. H. G. Knapp of the Indian Medical Service. Sir Dyce Duckworth remarked that patients with much uratic deposit were generally classed as examples of atonic Sometimes enormous deposits of urate occurred without any pain whatever. The condition of the urine might give no indication of progressive renal fibrosis, but it might contain sugar and in course of time a diabetic cachexia ensued in some of these patients.

Sir DYCE DUCKWORTH also gave details of a case of Gout with Uratic Tophi in a boy aged 14 years. He was indebted to Dr. H. Aldersmith, medical officer of Christ's Hospital, for the particulars of the case.

Dr. H. W. BAYLY gave a demonstration of the Treponema Pallidum in Syphilitic Lesions; of the Spirochæta Dentium in Carious Dentine; and of the Spirochæta Refringens in Balanitis.

Dr. W. P. HERRINGHAM read a paper on two cases of Pneumonia with considerable Displacement of the Heart simulating Pleural Effusion. He said that pneumonia was diagnosed partly by the physical signs and partly by the symptoms which it presented. If these were typical the diagnosis was easy. But in a large number of cases they were not. It was the physical signs that varied most, and in consequence the diagnosis had frequently to be made chiefly on the symptoms. But though it was comparatively common for the vocal vibrations to be absent, for the percussion note to be almost, if not quite, as flat as that of pleural effusion, and for the breath sounds to be weakened instead of undergoing the changes typical of pneumonia, it had never been his lot until the present year to observe along with these variations from the type such a displacement of the heart as would confirm the diagnosis of pleural effusion, though such displacement was not, of course, unknown.

Dr. N. S. FINZI and Mr. ERNEST H. SHAW communicated a further report on a case of Carcinoma of the Breast treated by Radium. The specimens which they exhibited were from a case of carcinoma of the breast shown to the Royal Society of Medicine on May 14th, 1909. The patient was a woman, began at the age of ten years with painless enlargement of the proximal joints of the fingers, followed by swelling of the ankles, elbows, and wrists. There was no pain for two years

X rays with temporary improvement. On March 10th and 12th, 1909, she was given two long exposures to the rays of 50 milligrammes of radium bromide filtered through This was followed by another exa thin silver tube. posure on April 29th, 1909, a screen of lead 1 millimetre in thickness being used in addition to the silver. The first two exposures were excessive and caused small but troublesome burns. The tumour and enlarged glands, however, disappeared and at the time of her death were not palpable. She was admitted to the German Hospital with a strangulated umbilical hernia and died on July 13th. At the post-mortem examination the whole of the mammary and axillary subcutaneous tissues was removed together with the portion of skin affected by the burns. The sites of the breast tumour and axillary swelling were seen to be occupied by two thin irregular sheets of fibrous tissue; no definite nodule of growth could be distinguished in the fibrous masses, but at the edge of the larger mass two small ovoid bodies about 1 centimetre in length were found which felt like pieces of hardened fat. There was no sign of any growth in the mediastinum, but there were several nodules about 1.5 centimetres in diameter in the liver. There were two whitish raised patches about 1 centimetre in diameter in the mucous membrane of the stomach. The kidneys, spleen, and other organs appeared to be normal. Dr. Finzi and Mr. Shaw considered that the microscopical sections they showed admitted of two interpretations: one, that most of the cells of the growth disappeared as the result of the radium treatment, but a few remained and afterwards began to multiply, some of them passing on to the lymphatic glands and liver; and the other that the growth was still being absorbed locally at the time of the patient's death. They thought that in favour of the first suggestion were the facts that the carcinoma cells, which were thickly packed in the fibrous tissue, were well stained and were "creeping" along, as it were, the fibrous septa into the surrounding fat; here they were not surrounded by fibrous tissue. Also the growth in the lymphatic glands was apparently recent, and there was no thick fibrous tissue. The liver nodule also had very little fibrous tissue between Dr. Finzi and Mr. Shaw believed that if further the cells. treatment had been given it might have completed the process of absorption of the growth. The condition of the skin due to the burns, however, rendered further treatment inadvisable.

MEDICAL SOCIETY OF LONDON.

Presidential Address.—Perforation of the Small Intestine.

A MEETING of this society was held on Oct. 11th, Dr. SAMUEL WEST, the President, being in the chair.

The PRESIDENT delivered his address, which is printed in

full on p. 1121.

Mr. Hugh Lett read a paper on two cases of Perforation of the Small Intestine. The first case was that of a woman, aged 54 years, who was admitted to the London Hospital on August 4th, 1906. Two days previously she was suddenly seized with severe pain in the upper half of the abdomen, followed by vomiting. She had suffered from dyspepsia for years, but had never had hæmatemesis. On admission the abdomen was distended, and moved only slightly on respiration; on palpation it was tender and resistant, especially on the left side in the upper half. The tongue was dry, the pulse was 120, and the temperature was 102° F. Perforation of a gastric ulcer was suspected, and laparotomy was performed. An incision was made through the upper half of the left rectus close to the middle line. When the abdomen was opened gas escaped, and the diagnosis of general peritonitis was confirmed. 18 inches beyond the duodenojejunal junction of the jejunum a small perforation was found, situated on the free border of the intestine, away from the mesentery. The wall of the intestine was thickened and infiltrated round the perforation. This was closed by a continuous suture placed transversely to the long axis of the intestine, and was finally covered in by a second continuous suture. A quantity of pus was discharged from the wound for some days after the operation, but the patient ultimately recovered. Mr. Lett thought that the cause of the thickening and perforation of the intestine was obscure. It could hardly have been carcinomatous, for the appearance was not in the least suggestive of carcinoma.

Nor was it probable that the condition was one of sarcoma. Tuberculous ulceration was, of course, possible, but improbable. The diagnosis of typhoid ulceration could not be entertained owing to the fact that the patient had been in her usual health until the time of perforation, also that such induration as occurred was not met with in typical typhoid ulcers. Besides, if the patient had recently been operated upon for gastric or duodenal ulcer, and a gastroenterostomy had been performed, there would have been no hesitation in describing the case as one of perforation of a peptic ulcer of the jejunum. In 1906 Gosset collected no less than 31 cases in which ulcers developed in the jejunum after this operation. In the last edition of Nothnagel, E. Wagner is quoted as having found an ulcer in the jejunum which resembled a duodenal peptic ulcer in a patient upon whom gastro-enterostomy had not been performed. Peptic jejunal ulcers might perhaps exist apart from gastro-enterostomy, and if so it was possible that the case described might be correctly considered one of a perforated peptic jejunal ulcer. The second case was that of a man, aged 45 years, who was admitted to hospital on June 26th, 1907. 15 hours before admission he had a sudden attack of severe abdominal pain; this was accompanied, or shortly followed, by a shivering fit, the temperature rose to 104° F., and the patient vomited several times. He stated that he had not felt well for five weeks. He presented an emaciated appearance and looked ill. The tongue was dry and red, the pulse was 110, the respirations were 40, and the temperature was 101°. The abdomen was uniformly rigid and painful, and hardly moved on respiration. Laparotomy was performed by an incision in the right iliac fossa. There was general in-flammation of the peritoneum, and its cavity contained purulent inoffensive fluid. A small perforation was found in the ileum two inches from the ileo-cæcal valve; there was no induration of the intestine round the perforation and the wall appeared to be rather thinner than usual. The perforation was closed by invaginating the gut transversely and inserting two layers of interrupted Lembert sutures. A tube with a gauze wick was passed into the pelvis and the wound otherwise was closed. The patient made an uninterrupted recovery. A large amount of inoffensive pus escaped from the abdomen for the first few days, but the tube was removed two and a half weeks after operation. The case was considered to be one of ambulatory typhoid fever with perforation. When the abdomen was opened three facts were discovered. The first was that the peritonitis was due to perforation of the small intestine. second fact was that this perforation was situated in the neighbourhood of the ileo-cæcal valve, where the great majority of perforations in typhoid fever are found. Thirdly, not only was the intestinal wall in the neighbourhood of the perforation free from any induration, but it also felt unusually thin for some distance above. The history of malaise and drowsiness during the preceding five weeks and the emaciated condition of the patient seemed to confirm the diagnosis. On the other hand, the serum agglutination test, which was carried out five days after the operation, was attended with a negative result. Taking the case as a whole, the diagnosis of ambulatory typhoid fever with perforation appeared to be the most probable one. Mr. Lett thought that the question of the pathology of the per-

forations in the two cases was of great interest.

A discussion ensued in which the following took part:
the President, Mr. V. Warren Low, Dr. F. DE HAVILLAND
HALL, Dr. C. S. DE SEGUNDO, Mr. T. H. KELLOCK, Dr. A. F.
VOBLCKER, and Dr. H. DANVERS, after which Mr. Left
replied.

MEDICO-CHIRURGICAL SOCIETY OF GLASGOW.—The first meeting of the session of this society was held on Oct. 1st, when Professor Robert Muir delivered his presidential address, taking as his title "The Doctrine of Inflammation." He pointed out that confusion and inaccuracy prevailed both in pathological and in clinical work owing to the want of a generally accepted definition of the term. He briefly sketched the history of the subject, indicating the different points of view from which inflammation had been regarded. Increased knowledge of the histological changes and of the nature of the causes of inflammation supplied by bacteriology had not removed the difficulty. The views of writers on pathology were compared. Some regarded inflammation as essentially defensive; others as in the main

the result of damage; others stated that it is a complex process incapable of definition; some included reparative processes under the term; others excluded them. He stated that the chief reason for the difficulty in obtaining agreement amongst authorities was the fact that inflammation is not a single process but represents a collection of processes which differ in nature. In considering this statement he took the meaning of the term "process"-i.e., a biological process, to be a succession of changes more or less similar in object. The physiological processes were divided into two great classes: (1) the functional, in which living matter was broken down; and (2) the nutritional and formative, these corresponding respectively to the katabiotic and bioplastic of Weigert. These are essentially different in nature and they are found together often in inverse proportion to each other at different periods of life and under varying circumstances. The pathological processes closely correspond, with the addition of one great class, thus: (A) retrogressive processes—necrosis, degenerations, &c., the direct result of damage; and (B) reactive or progressive processes—defensive and reparative—including (a) increased functional activity—e.g., phagocytosis; and (b) increased formative activity, proliferation of cells, &c. The pheno-The phenomena of acute inflammation were then analysed according to this scheme. The slowing of the blood stream, stasis, and diapedesis of red corpuscles must be regarded as directly due to damage done to the capillary endothelium. Until the nature of lymph formation is satisfactorily settled a decided opinion cannot be expressed with regard to the exudation, but most of the facts point to its being the result of damage to the vessel wall. As to its results, these are in part beneficial, in part harmful. Practically all are agreed that the migration and subsequent movement of leucocytes, and the phagocytic and secretory properties of these cells, constitute a defensive process—increased functional activity. Phagocytosis by endothelial and connective tissue cells is to be similarly regarded. Proliferation of these cells was also discussed. The general result of such an analysis is that there is a multiplicity of processes of different nature. Phagocytosis by leucocytes and other cells may in a sense be regarded as the most important phenomenon, but if so it has no relation to any of the cardinal symptoms of inflammation. When we come to consider the subacute and chronic procasses the difficulty increases. The presence of certain parasites produces, in addition to a leucocytic reaction, proliferation of connective tissue cells and the formation of new blood-vessels: in other words, leads to the formation of granulation tissue similar to that seen in the healing of wounds. Is this process in the two cases to be considered the same in nature or of two kinds? It is unjustifiable to extend the term "inflammatory" to the healing process which essentially depends upon breach of continuity of the tissuesthat is, a variety of regeneration. Inflammatory prolifera-tion may be the result of damage—i.e., reparative, and not the effect of direct stimulation, but this is not proved. is better to speak of it simply as being the result of irritation; whether this acts directly or indirectly must be left an open question. In any case the use of the term "inflammatory" serves no useful purpose. The same holds true tory" serves no useful purpose. The same holds true with regard to the fibroses. Some are due to con-The same holds true tinued mild irritation, some are simple replacements, and some are of functional significance, but whether they are inflammatory or not depends entirely upon the definition. The necessity for analysis is equally great in connexion with the treatment of inflammation. this connexion, again, inflammation is not to be regarded as a process: treatment is not directed towards it as a whole. Rach therapeutic measure is applied to some part of the complex, and is so applied according as to whether the process in question is to be checked or encouraged. methods of treatment were considered in this relationship. The general conclusion arrived at was that it is impossible to define inflammation and at the same time to maintain its relations to the recognised cardinal signs. It should only be used as a convenient, though somewhat indefinite, clinical term, and its use in matters of discussion should be avoided.

BRIGHTON AND SUSSEX MEDICO-CHIRURGICAL SOCIETY.—A meeting of this society was held on Oct. 8th.—Mr. R. F. Jowers showed a case in which Facial Paralysis, following on a radical mastoid operation within a few hours, was successfully treated by facial-accessory nerve anastomosis. The operation was performed three months after the mastoid

was treated.-Dr. W. Broadbent showed a woman suffering from Myxœdema; she improved greatly with thyroid treatment and relapsed directly she omitted it.—Mr. H. H. Taylor showed a girl with Rupture of the Choroid from a blow on the eye with a piece of wood and a case of Primary Optic Atrophy in a man the subject of early locomotor ataxia.—Mr. G. Morgan showed (1) a case of Hypertrophy of the Right Breast in a male child, two years old; and (2) a case of Ganglion of the Biceps Tendon of the arm in a young woman. He also read the notes of a case of Unusual Gland Disease. A more or less universal swelling of the glands occurred in a male, the case presenting all the appearance of Hodgkin's disease. However, it all cleared up with fresh-air treatment, and the diagnosis therefore remained uncertain. It was suggested it might, in spite of the number of glands affected, have been tuberculosis.—Mr. A. G. Bate read the notes of a case of Amputation at the Hip-joint on a man, 73 years of age, who had suffered from Tuberculous Necrosis of the Femur for 60 years and had had numerous operations. The result was quite satisfactory.—Dr. E. Hobhouse showed a Sarcomatous Liver, weighing 72 ounces, from a child aged six years; also (for Dr. J. F. Gordon Dill) a specimen of Lympho-sarcoma of the Spleen in a young man. He also read a paper on Recent Advances in our Conceptions of Heart Disease, for which a vote of thanks was accorded by the society.

Rebiews and Aotices of Books.

Bulletin of the Committee for the Study of Special Diseases.
Edited by T. S. P. STRANGEWAYS, M.R.C.S. Eng.,
L.R.C.P. Lond., "Huddersfield" Lecturer in Special
Pathology in the University of Cambridge. Vol. II.
Published by the Committee and printed at the University Press, Cambridge. Pp. 179. Price 21s. net.

This number contains the report of the committee for the year 1907, which has been delayed in order that an account might be given of work begun in that year but only recently completed. The following papers and monographs are appended: 1. The Arterial Blood-pressure in Arthritic Diseases, by Dr. J. Lambert. The results of sphygmomanometric observations by means of Dr. G. Oliver's instrument in the various forms of rheumatoid arthritis, gout, and in toxic varieties of chronic joint lesions are recorded. It is stated that the pressures in the acute and subacute forms of progressive rheumatoid arthritis are subnormal or normal, in the chronic progressive form normal, and in the senile high and often supernormal. In acute and subacute gout the pressures may be normal or subnormal, due allowance being made for the age of the patient and for the duration of the disease. Hyperpiesis is met with in cases of arthritic gout. The pressure in chronic tophaceous gout is higher than in the other forms. Low pressure is often met with in cases of toxic arthritis, such as gonorrhœal, rheumatic, tuberculous, and septic forms. Senile osteo-arthritis and osteitis deformans are generally associated with raised pressures. A bibliography and some charts are appended. A Report on Some Points in the Etiology and Onset of 195 Cases of Rheumatoid Arthritis, by Dr. J. Lambert. The family history, civil state, sex, age at onset, nature of onset, the first joint attacked, and the association with other diseases were considered in relation to the disease. extension of this report deals with the family history and clinical features of 125 cases of gout. In the same report is included a paper by Dr. James Lindsay on the relation of infective foci to rheumatoid arthritis. It deals with 172 cases of rheumatoid arthritis, of which 138 were females and 34 males. The striking result was found that a definite source of infection preceding the disease was recorded in 73 females and 15 males, an association which Dr. Lindsay regards as due to more than coincidence. 3. The Ophthalmic Reaction: Some Observations on 10,000 Collected

Cases, by Mr. Constant W. Ponder. On the basis of his own observation of 97 cases and of cases recorded in the literature Mr. Ponder concludes that the test must depend upon some specific reaction, but that in view of the marked variability in the hands of different observers there must be some factor or factors which often falsify the results obtained, and that until the nature of this has been determined the test can only be relied upon to give a somewhat broad opinion rather than a decisive diagnosis. Appended to this report is a note on the conjunctival reaction to tuberculin in arthritic diseases by Mr. T. S. P. Strangeways. The observations were undertaken in view of the description by Poncet of "rhumatisme tuberculeux." The reaction was tested on 340 cases of arthritis of a type clinically nontuberculous. A positive reaction was obtained in 210, or · 62 per cent. of the cases. Six of the cases subsequently came to necropsy, but the results were such as to throw doubt on the value of the reaction. 4. Report on a Case of Hypertrophic Pulmonary Osteo-arthropathy, by Mr. Strangeways and Mr. Ponder. The condition was associated with an intrathoracic malignant growth, described as an endothelioma. Full details are given of the clinical history and of the post-mortem appearances as well as excellent skiagrams. 5. Observations on Purin Metabolism, by Dr. H. Ackroyd. As a result of a laborious research regarding the variations of the endogenous and exogenous purin excretion in healthy persons and in cases of rheumatoid arthritis he finds that there is no important change in the purin metabolism in persons suffering from this condition. An acute or subacute attack is accompanied by an increased purin metabolism in some cases, but not in all.

The scientific study of special diseases in the manner carried out by the committee is one which is worthy of every encouragement, and the laborious work entailed is bound to yield useful practical information eventually. We have nothing but praise for this volume.

The Law of Compensation for Industrial Diseases. By EDWARD THORNTON LAWES, M.A., B.C.L., of Lincoln's Inn and the Western Circuit, Barrister-at-law, Recorder of Salisbury. London: Stevens and Sons, Limited. 1909. Pp. 306. Price 7s. 6d.

This book is described in an explanatory sub-title as "an annotation of Section 8 of the Workmen's Compensation Act, 1906, with chapters upon the powers and duties of certifying surgeons and medical referees, and the rules, regulations, and forms relevant thereto, and including a special treatise upon every disease to which the Act now applies, together with the special rules or regulations made under the Factory and Workshop Acts for the prevention of such diseases." Tempora mutantur, and of the changes wrought in our social conditions during recent years this work serves as a notable reminder. If we can imagine a common-law barrister or a manufacturer to have dropped asleep 30 years ago in his chambers or his counting houses and to have been awakened by the descent of Mr. Lawes's volume upon the table beside him, we may go further and try to picture his bewilderment on turning over its leaves. It contains more than 300 pages of statutes, regulations, forms, and explanatory comments upon a subject entirely new to him, the Rip Van Winkle of the law courts or the merchant's Whether it be the lawyer or the employer whom we have conjured up, he has been familiar with the doctrine of "common employment" and the principle involved in the words "volenti non fit injuria." He has probably looked upon them as bulwarks of defence likely to outlive the Magna Charta, and upon industrial disease as the inevitable risk undertaken by the worker in consideration of the wage paid to him.

He awakes to find that an "Employers' Liability" Act dealt the first blow at the position once impregnable, and that successive statutes providing for "Workmen's Compensation" have followed up the attack, each widening the breach made by its predecessor, and all alike denying to master and man the liberty to contract out of their respective liabilities and rights. He then proceeds to realise that not only are "accidents" to workmen, as he understands the word, the subject of compensation, but that a large number of industrial diseases are treated by the law as "accidents." He may at first be inclined to think that this novel development of the meaning of a familiar term lays an undue burden upon employers, but perhaps as he reasons the matter out he will come to the conclusion that the obligation to compensate for disease is less likely to imply injustice than are many claims arising out of alleged accidents of the more familiar class. The industrial disease is more readily traceable to a preventable origin, and produces, as a rule, symptoms more independent of the verbal statement of the sufferer and less likely to be feigned or exaggerated than the supposed strain or concussion. This volume contains rules which the employer must observe if he is employing men in a dangerous trade, the breach of which will render him liable to legal proceedings apart from any immediate result which his conduct may bring about. It also contains an account of the dangerous processes, and of the pathology and symptoms of the diseases arising from them. This introduction of details of manufacture and medicine into a legal text-book is new to us, and at first sight seems out of place, but we are bound to say that the combination of professional wisdom produces a practical guide to the subject. We note in this connexion that the author has compiled this portion of his work from authoritative sources, and that he acknowledges valuable assistance from Dr. B. A. Whitelegge, Chief Inspector of Factories, and Dr. T. M. Legge.

To lawyers, to employers in dangerous trades, and to medical men as medical referees or certifying surgeons, or, indeed, in any other capacity, we have no hesitation in commending Mr. Lawes's volume.

Tuberoulin in Diagnosis and Treatment. By Dr. BANDELIER, Senior Physician to Dr. Weicher's Sanatoria for Pulmonary Disease in Görbersdorf, and Dr. ROEPKE, Medical Director of the Sanatoria for Railway Employees in Melsungen. Translated from the second German edition by EGBERT C. MORLAND, M.B., B.Sc. Lond., M.D. Berne. London: John Bale, Sons, and Danielsson, Limited. 1909. Pp. 182. Price 7s. 6d. net.

This work is designed as "a text-book of the specific diagnosis and therapy of tuberculosis for practitioners and students." It gives a good picture of the position of tuberculin in German medical practice at the present day. Discretion was given by the authors to the translator (Dr. Morland) to add material suitable for an English edition. We think, however, that he came to a wise conclusion when he decided simply to render the book into English, as he considered the time not yet ripe for a judgment on the methods of vaccine therapy now obtaining in England — methods largely arising from Sir Almroth Wright's brilliant researches into the mechanism of immunity.

The first portion of the work is devoted to a consideration of the specific diagnosis of tuberculosis by means of tuberculin; the cutaneous, percutaneous, conjunctival, and subcutaneous methods are described and criticised. In describing the cutaneous reaction the authors express the opinion that the diagnostic certainty of the test is extraordinarily great. They state that if the cases at death's door are excluded, the percentage in the various stadia of the disease varies within such narrow limits that it may be held to be a constant. They quote von Pirquet's statistics, which showed that 97 per cent. of the positive reactions exhibited undoubted naked-eye appearances of tuberculosis at the necropsy, whereas all the children who were found on the table to be free from tubercle had given a negative reaction. The subcutaneous method is held in this work to be par excellence the diagnostic agent for the detection of early pulmonary tuberculosis in adults. Its value is considered to be increased by the fact that in a high percentage of subcutaneous tests focal reactions make their appearance and allow a conclusion as to the site of the tuberculosis in the lung.

In the second portion of the book the specific treatment by tuberculin of pulmonary tuberculosis is first discussed, and an interesting account is given of the results which have been achieved in Germany. It has recently been proved that minute doses of tuberculin, such as Toologoth of a milligramme, and even smaller, produce decided effects, but Dr. Bandelier and Dr. Roepke maintain that such small doses are inadequate, basing their opinion on the view that the action of tuberculin rests partly on a systematically acquired tolerance, a gradually acquired immunity to the toxin. They therefore argue that the aim in the use of tuberculin should be to reach the maximum dose, and in some of their cases as much as 1000 milligrammes were given in one dose. We do not consider that the cases they record are convincing, inasmuch as they were all afebrile at the time the treatment was commenced. That no reaction should occur after such a large dose as that mentioned above is certainly interesting, but judging by clinical tests excellent results are obtained by the more simple methods of treatment during the afebrile stage, although we admit that we should not care to submit cases of apparently complete arrest to such heroic tests. The authors' remarks on the results of treatment by tuberculin are confusing, inasmuch as they distinguish between "cure" and "improvement." In the present state of knowledge the use of the word "cure" in connexion with pulmonary tuberculosis is of doubtful wisdom, and the term "arrest" is preferable. That the authors themselves saw the difficulty is shown by the following statement: "Definitely progressive forms of disease need not be considered for tuberculin treatment, nor is much to be expected in the case of advanced processes, where much destruction of lung tissue has taken place." Yet two pages further on we read: "Based on our own experience, we should say that, setting aside the severe incurable forms of consumption, especially cases of severe mixed infection with pyrexia, every uncomplicated case of pulmonary tuberculosis may be submitted to the mild method of tuberculin injection, avoiding as far as possible all reaction." The first quotation applies to the possibility of "cure," the second to the possibility of improvement, relief, or "arrest" of the disease. The results obtained by several observers in this country point in the direction of the advisability of small doses given in accordance with the temperature chart, and would therefore more nearly accord with the second of the above opinions. It will be a matter of interest to watch further researches in this matter; it is only by increased experience and watching the cases over long periods of time that any definite conclusions can be arrived at as to the most advantageous methods of administering tuberculin as a therapeutic measure in cases of pulmonary tuberculosis.

The treatment of tuberculosis of other organs than the lungs by means of tuberculin is then discussed and favourable results are claimed in cases of tuberculous peritonitis. The whole work is well worthy of attention. The true value of tuberculin has not yet been established, but the

results hitherto obtained are decidedly encouraging, and' there is every hope that the issue of the large amount of clinical work now being done on the subject will be in accordance with these good promises.

The Open-air Treatment of Pulmonary Tuberoulosis. By F. W. BURTON-FANNING, M.D. Cantab., F.R.C.P. Lond., Physician to the Norfolk and Norwich Hospital; Honorary Visiting Physician to the Kelling Open-air Sanatorium. Second edition. London: Cassell and Co. 1909. Pp. 184. Price 5s net.

DURING the four years that have elapsed since the publication of the first edition of this book the principles of the open-air treatment have become more universally accepted and new elements have been introduced dependent upon our more advanced knowledge in acquired immunity. Dr. Burton-Fanning has brought his little work fully up to date, and has studied with an open mind the latest researches which have a bearing on his subject. A good and detailed account is given of the daily routine to be followed in carrying out the open-air treatment, especial emphasis being laid on the deductions which may be drawn from the temperature chart. We agree with the author in maintaining that for all clinical purposes the oral temperature may be relied upon, so dispensing with the inconveniences inseparable from taking the rectal temperature. The transitory rise of temperature which occurs after exercise in healthy individuals may only be detected in the rectum, and if the mouth temperature be relied upon such a rise may not be detected; a persistent elevation of temperature after exercise, however, such as is sometimes seen in tuberculous individuals, has altogether a different significance, and if an interval of half an hour be allowed the mouth may be depended upon for its recognition.

The recent observations which have been made on the opsonic index in relation to tubercle are fully discussed, and the important part which auto-inoculation has been shown to play in patients suffering from active tuberculosis is explained in detail. The system of graduated labour, which has been fully described in our columns, is favourably commented on. Dr. Burton-Fanning considers that this method is the best introduced in the case of "afebrile consumptives." Those of our readers who wish to consult a shortwork in which the chief points in the open-air treatment of pulmonary tuberculosis are ably and clearly described and discussed cannot do better than refer to this book.

Blackwater Fever (Bilious Malignant Tortian Ague). By A. G. NEWELL, M.D. Glasg., D.P.H. Camb. London: John Bale, Sons, and Danielsson. 1909. Pp. 127. Price 5s. net.

This little book has been prepared to set out the views of its author on the condition known as blackwater fever. Dr. Newell has practised his profession for some nine years or more in highly malarious districts of India, more particularly in the Duars, where blackwater fever is often met with, and where. our readers may remember, Captain S. R. Christophers, I.M.S., and Dr. C. A. Bentley carried out their well-known investigations which were published in No. 35 of the "Scientific Memoirs of the Medical and Sanitary Departments. of the Government of India," reviewed in THE LANCET of Feb. 20th of this year. The author claims, therefore, to know something of blackwater fever, the more so since he has had an attack of the disease himself. His views briefly are based on the consideration that "in every case of blackwater fever there will be found antecedent to it malaria, an attack of malignant malaria fever, and a congested liver." The disease, therefore, in his opinion is simply malignant tertian malaria with a superadded biliary condition by which the already congested liver is unable to deal with the destroyed blood corpusoles and the hæmoglobin;

consequently nature, to relieve the liver, excretes the hæmoglobin by other organs—namely, the kidneys; hence the hæmoglobinuria. He therefore formally defines blackwater fever to be "an acute complication of hæmoglobinuria occurring in a patient affected with the malignant tertian parasite of malaria, in whom congestion of the liver has proceeded so far as to incapacitate the liver from dealing with the destruction of red-blood corpuscles, and hæmoglobin emitted therefrom, and which congestion and inactivity of the liver might be exaggerated by a sudden chill or sudden dosage of quinine." Dr. Newell urges that the name "blackwater fever" should be abolished, and the term "bilious malignant tertian ague" substituted. The author takes a somewhat sanguine view of the prognosis in cases of blackwater fever, for under the paragraph headed Mortality he adds "there should be none. The disease is preventable. If taken early judicious treatment should save all." Of the total 127 pages comprised in the book 42 are devoted to the author's arguments in favour of his "theory" respecting blackwater fever: 40 pages are given to the clinical details of some five illustrative cases, while 45 are given to the appendices, which include particulars of laboratory methods for staining films and identifying malaria parasites, the anatomy of mosquitoes, the pharmacology of quinine, preventive measures against blackwater fever, and a variety of other matters. As frontispiece to the book is inserted a photograph of a boy in an advanced state of emaciation from kala-azar who was under Dr. Newell's treatment as a patient. There is evidence suggesting that the book has been somewhat hurriedly prepared for the press. On the title page it is stated that Dr. Newell is editor of Indian Public Health, and this makes it more surprising that certain terms and expressions should have been allowed to pass uncorrected. For instance, it is unusual to find in a medical work the term "off his feed" when the writer is signifying that the patient has anorexia; and objection may well be taken to the employment of the popular phrase "a chill on the liver" in a book intended for medical and scientific readers.

LIBRARY TABLE.

Essentials of Medicine: a Text-book of Medicine. By CHARLES PHILLIPS EMERSON, M.D., late Resident Physician, the Johns Hopkins Hospital. Illustrated by the Author. London and Philadelphia: J. B. Lippincott Company. Pp. 383. Price 8s. 6d.—This work, which is written in popular. rather than in strict scientific, phraseology, is intended "for students beginning a medical course, for nurses, and for all others interested in the care of the sick." The various organs of the body are considered seriatim, and a brief account is given of the physiology of each, and the principal morbid conditions which may affect them. Students may find it useful when first entering upon the study of medicine after having passed the preliminary examinations in anatomy and physiology. Nurses also who desire to take an intelligent interest in their work will find much that will be useful to them by studying Dr. Emerson's remarks, and will not be needlessly encroaching on those matters which concern only practitioners of medicine. The book will serve as an introduction to the more detailed text-books on pathology and clinical medicine.

Infant Feeding by Artificial Means. By S. H. SADLER. Third edition. London: George Routledge and Sons, Limited. New York: E. P. Dutton and Co. 1909. Pp. 253. Price 3s. 6d.—It would, in our opinion, have been wiser to allow this little book on infant-feeding to remain in obscurity. At no time did it serve any useful purpose, much less does it do so at the present moment when a large section of the intelligent public take the subject with which it deals with a considerable amount of seriousness. The preceding edition was published in the

year 1896. Since that date infant-feeding has been reduced if not to an exact science, at least to a scientific art, but the third edition of Mrs. Sadler's work, which lies before us, is merely a reprint or republication of the crude and inexact compilation of 1896. We have compared the two editions carefully and we detect no differences, except that in the present edition there is a six-page appendix, the first half of which is a digest of an article from the pen of Sir Almroth Wright published in THE LANCET of July 22nd, 1893—which certainly ought to have been included in the last edition, while the second half is an article on "The Modern Use of Asses' Milk in Infant Feeding." This article is no ornament to the book; it is written by M. Nicolas Riotte, "Fournisseur des Hôpitaux," and in spite of the fact that the directness of the appeal is somewhat mitigated by the elegance of the original French, it is little less than a commercial advertisement of the milk he furnishes to the hospitals. reader would no doubt appreciate an explanatory note on the statement that "asses' milk is of a very volatile nature" and always should be given to the infant immediately it is taken from the ass. Returning again to the body of the text which has been reprinted or republished, we cannot help drawing attention to the undesirability of there appearing in the pages of a book which is intended to instruct the ignorant an illustration and a description of a "tube-bottle"; if this was an offence in 1896, it is almost a crime in 1909. Mrs. Sadler says, "almost all medical men are against using cream diluted with water" as an exclusive diet for an infant. Surely this was not true even in 1896? Had we not considered this little book likely to prove a most dangerous instrument of instruction in the hands of a young and ignorant mother we should have hesitated to emphasise defects in the work which are obvious to anyone acquainted with the rudiments of infant-feeding.

The Prodigal Father. By J. STORER CLOUSTON. London: Mills and Boon, Limited. 1909. Pp. 303. Price 6s. -Mr. Storer Clouston has again written a thoroughly amusing story. To the end of his career he may suffer from the great and well-deserved success of "The Lunatic at Large," because his readers will always compare whatever he does with that drollest of stories, and will be trying him by a standard which any author must always have difficulty in reaching. Frankly, we do not consider that "The Prodigal Father" is as funny as "The Lunatic at Large," because the means employed to produce the farcical situations call for too much credulity from the reader, while in the earlier book the wildest extravagances of the charming maniac and his absurd German friend could be believed in without demanding us also to believe in the suspension of ordinary physical laws. "The Prodigal Father" is the story of a parent who underwent unorthodox medical treatment which had the effect of making him grow younger, the transformation taking place gradually, and not suddenly as in the classic case of Mr. Bultitude. A number of absurd situations are produced, but Mr. Clouston's protagonist, unlike Mr. Bultitude, is always on the winning side. He undergoes no humiliations, he triumphs successfully in some tight social places, and having started on the first page as a respectable merchant of advanced middle age, is found on the last page requesting to be sent to a good school. We congratulate Mr. Clouston upon his wit and high spirits, and recommend the book to our readers as a diversion and not as a therapeutical note.

JOURNALS AND MAGAZINES.

moment when a large section of the intelligent public take the subject with which it deals with a considerable amount of seriousness. The preceding edition was published in the

M.A., F.R.S., and E. A. MINCHIN, M.A. With lithographic plates and text figures. New Series, No. 213 (Vol. LIV., Part I.). London: J. and A. Churchill. 1909. Price 10s. net. -This number contains the three following memoirs: 1. The Development and Origin of the Respiratory Organs in Araneze, by F. W. Purcell, Ph.D., of Bergvliet, near Cape Town, with seven plates and seven text figures. The lungbooks of Arachnidæ have been regarded as gills, and then as a special form of trachea, and finally as being of branchial origin. Dr. Purcell's investigations were made on 41 species chiefly collected in the neighbourhood of Berlin, and especially the embryos and young of Sitticus (Attus) floricola. He gives a table showing the homologues of the abdominal appendages and their derivatives in scorpions, tetrapneumonous araneæ, dipneumonous araneæ, pedipalpi and in the Japanese limulus. He corroborates the statement in a previous communication that none of the lungbooks in scorpions are actually homologous with the two pairs in spiders, and further that the two pairs of lung-books in spiders are represented by external appendages in the adult scorpion, and the two anterior pairs of lung-books in the latter by external appendages in the adult spider. Further, he is of opinion that the lung-books of the scorpions and those of the spiders must have been derived from branchiate appendages quite independently of each other, and that the terrestrial arachnids are not monophyletic, but must have had at least a diphyletic origin from primitive aquatic arachnida with six pairs of abdominal branchiate appendages on the eighth to the thirteenth somites. Lastly he considers that the pulmonate arachnids comprise two distinct groups which have separately originated from branchiate ancestors: (1) the scorpionidæ; and (2) the araneæ and the pedipalpi. He agrees with Pocock that the scorpiones, although the most primitive of all of the terrestrial arachnida, could not have been the ancestors of any other orders of arachnida because the useful tail would not be likely to be lost. He adds that so far as our knowledge goes we may say that there is no evidence of any sort to indicate that the spinners of the araneæ were derived from sunken-in lung-books or that the spinous segments ever possessed such organs in any ancestral form of this order. Numerous and excellent drawings illustrate the various points to which reference is made. 2. Notes on the Nephridia of Dinophilus and of the Larvæ of Polygordius, Echiurus, and Phoronis, by E. S. Goodrich, F.R.S., Fellow of Merton College, Oxford, with a plate. 3. Further Notes on a Trypanosome found in the Alimentary Tract of Pontobdella Muricata, by Muriel Robertson, M.A., Carnegie Research Fellow, with a plate and five textfigures.

The Bristol Medico-Chirurgical Journal.—I the September number of this journal is published an interesting article by Mr. Ernest W. Hey Groves on Tuberculosis of the Colon, which he divides, following Hartmann, into an enteroperitoneal and a hyperplastic form. The condition is not very common and is of considerable interest as being often confounded with cancer. Mr. Groves reports two cases of the condition—one of which recovered after operation, while the other finally succumbed. Dr. J. M. Fortescue-Brickdale contributes a paper on Some of the Modern Hypnotic Drugs, which he classifies according to their clinical features. Dr. P. Watson Williams writes on Some Points in the Technique of the Radical Operation for Chronic Purulent Otitis Media, Dr. F. G. Thomson on Referred Cardiac Pain, and Dr. George H. Almond on Theoretical Considerations as to Pulmonary Percussion.

The Birmingham Medical Review. - The publication of Dr. David Fraser Harris's lectures on the essentials of physiological history is continued in the August issue of this review. The present instalment deals with the history of | to be held in Paris next year.

our knowledge of the nervous system, which was practically founded by Galen, and was carried on by the Alexandrines, and later by the school of Bologna. Of our own countrymen Willis, Hales, Bell, and Marshall Hall are honourably mentioned, but until recent years research in this field was apparently not much advanced in these islands.

Looking Back.

FROM

THE LANCET, SATURDAY, Oct. 15th, 1881.

COMMON PRACTICE IN IRELAND OF GIVING DIGITALIS IN EPILEPSY.

To the Editor of THE LANCET.

SIR,—Having acquired much useful information from your invaluable Journal during the last four years while pursuing my medical education in this metropolis, and knowing that your liberal pages are as open to the humble letter of the student as to the scientific communications of the more experienced members of our profession, I am induced to make a few remarks on the use of digitalis in the treatment of epilepsy, corroborative of Dr. Sharkey's statements, which appeared in THE LANCET of the 7th of August last.

It is a fact well known to most medical men practising in Ireland, that the peasantry are well acquainted with the efficacy of digitalis, or luss more, as they call it, in the cure of epileptic children. When the poor child becomes subject to this distressing affection, it is considered to be fairy-stricken, i.e., that the child has been taken away, and an old fairy sent in its place. The unfortunate being is then neglected, the extremities waste away, the abdomen is generally tumid, and the features actually assume the appearance of old age. A consultation of old women is held, with a ban lieughth, or woman skilled in herbs, as president. The fairy is counselled to leave the house quietly, and send back the people's child. If he continue obstinate, they first threaten him with the milder punishment of placing his breech (the "pelvic extremity" of -) on a red-hot shovel, or roasting him at the fire. These threats being disregarded, and the fairy's presence being still ascertained by the recurrence of the fits, he is at last doomed to take the digitalis, a dose considered most obnoxious to the fairy tribe. A handful of the fresh leaves is boiled in milk, and the decoction is strained, and when cold, poured down the poor fairy's throat, vi et armis. The consequence is, in nine cases out of ten, that a cure is effected, the child soon recovers its natural strength and appearance, and the parents believe that the luss more has banished the fairy, and that their own child is restored to

Should you, Mr. Editor, honour me by giving these remarks a place in your widely-circulated Journal, you will confer a favour on one who, in common with his fellow labourers in the pursuit of science, has always found you their advocate and friend.

I have the honour to remain, Sir, Your obedient servant, A MEDICAL STUDENT.*

* Our correspondent has enclosed us his name and address. - ED. L.

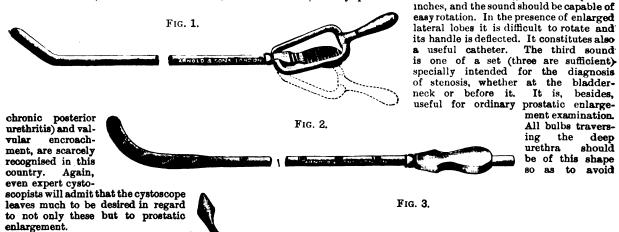

SCHOOL HYGIENE IN BRIGHTON.—The Brighton education authority has recently been showing increased interest in the hygiene of the children under its control, and has made the study of hygiene a separate subject in the school curriculum. The committee has informed a member that it will take into consideration the question of open-air schools, and Dr. J. Lambert, the school medical officer, has received an instruction to visit as an experiment the homes of any children reported to be suffering from tuberculosis and to report to the committee at the expiration of three months. The same gentleman and Mr. H. Gervis, a medical colleague on the education committee, have been appointed delegates to the International Congress on School Hygiene which is

SOUNDS FOR THE DIAGNOSIS OF OBSTRUCTIONS AT AND ABOUT THE BLADDER-NECK.

THE anatomy of these obstructive states is important to flat and broad where it lies in the prostatic urethra. Indetermine. Some, such as fibrous stenosis (so common after healthy parts urine should flow at eight and a quarter

traverse the healthy urethra in all directions without deviation. I withdraw it by the small handle shown in the frame. The second instrument is a long, hollow, graduated sound, flat and broad where it lies in the prostatic urethra. In healthy parts urine should flow at eight and a quarter

The sounds illustrated have been of much use to me for years past. I offer them as being simple, useful, inexpensive, and requiring no technique.

cal skill. The first is a modification of the ordinary sound. An old and well-known aid to determine enlarged "middle" lobe was the withdrawal of a sound in the axis of the urethra, when its deviation afforded some evidence. The test is unfair and rough, whereas the use of the sound shown will prove of real use. It should

hitching on the layers of the triangular ligament on withdrawal. The instruments are made by Meesrs. Arnold and Sons, West Smithfield, London, E.C.

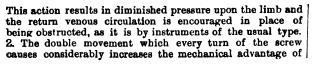

JAMES MACMUNN, M.R.C.P. Irel., M.R.O.S. Finsbury-pavement, B.C.

A DOUBLE-ACTION ALAR TOURNIQUET.

This tourniquet, as its name implies, is a double-action one and appears to present several distinct advantages over similar instruments in previous use. 1. The motion of screwing down the pad on the wounded vessel at the same time raises two metal wings at either side of the instrument.

the latter. The vessel is thus rapidly compressed by a few turns of the screw. 3. The bearing points of the instrument are so far apart that the skin cannot be nipped up between them, however rapidly it is applied. In use the pad should be applied directly over and parallel to the course of the vessel and the tape should be well tightened around the limb before the instrument is screwed down.

The instrument is made by John Weiss and Son, Limited, 287, Oxford-street, London, W.

The Limitations of Operations.

THE progress of surgery during the last 30 years has been vast, and the results have been marvellous, so that it is hardly surprising that the idea has arisen in some minds that surgery has no boundaries, and that it will yearly spread more widely mainly at the expense of medicine until it forms almost the whole of the healing art. Dr. OSLER has just called our attention to the fact that the developments of medicine proper have been equally great, which is in other words a reminder to us that surgery has its limitations. Wonderful though its progress has been, and great its achievement, yet it must be acknowledged that in many ways it has limits beyond which it cannot pass. It can no more than medicine set aside the influence, for example, of old age when the reparative powers are to a great extent impaired. It is true that even in advanced age a broken bone will heal in most cases as quickly and as thoroughly as in a young child, but many tissues show a slackness in repair that betrays the harmful effect of old age. The wrinkled soft skin of the aged is typical of many of the tissues, and where elasticity should be specially marked there we find it most noticeably absent; for instance, ligaments lose their lissomness. But the chief change is seen in the arteries, where calcareous salts have been deposited both in the inner and the middle coats. The one-time highly elastic vessel has become a rigid tube. This is a potent factor in limiting the operations which can be performed on the old. In THE LANCET of Sept. 25th we recorded an operation done for the first time in a human being, consideration of which has led to these comments, for it seems to us that the experiment was one the result of which cannot be taken as a general lesson in surgery owing to the age and condition of the subject.

In consequence of a commencing gangrene of the foot in a feeble old man, 69 years of age, Mr. D. J. ARMOUR and Mr. E. A. SMITH performed arterio-venous anastomosis of the femoral vessels in order to carry blood to the limb through the vein. The patient was no loser by the brave attempt at conservative surgery. The arteriovenous anastomosis was successful, a result which does great credit to the ingenuity of the operators, but the attempt to save the limb failed, and those who read the account cannot doubt that the main cause of this failure was the rigidity of the arteries owing to calcareous degeneration. This is so common an accompaniment of old age that it must diminish to a very great extent the possibilities of operating. Even in many of those who can hardly be called aged rigidity of the arteries exists to a certain degree, and though its importance varies much with the operation to be performed it must

to a greater or lesser extent weigh against the desirability of operating at all. The inability of accommodating itself to the varying needs of the tissues which it supplies is the cardinal fault of a rigid artery, and an operation gives rise to great variations in the amount of blood-supply. General feebleness of a patient, too, is another important factor in limiting the surgeon's power of operating, but this, unfortunately, cannot always be taken into full account by the surgeon who most usually has to recognise that death will close the scene unless he interferes. Everyone knows that the risks of an operation are vastly increased if the patient is not in a condition to withstand the shock of the operation itself or the depression which so commonly follows in its train, due partly to loss of blood and partly to the influence on the nervous system. In some conditions of ill-health the body, as a whole, and the individual organs and tissues, show no resilience after the shock of the operation; they fail to respond to the demands made on them, and attempts at repair are almost wanting. In such conditions as these, rare fortunately in a marked degree, but by no means uncommonly seen slightly developed, the efforts of the surgeon are heavily handicapped, as they are when he has to operate in the presence of serious disease of important organs. Of one of the most serious hindrances to operation, hæmophilia, we may also say a few words. However skilfully the surgeon has performed the operation the tendency to bleed will assuredly prevent success, and therefore it has been the rule never to operate on a known hamophiliac unless the operation is absolutely essential to life. But recently it has been reported that the injection of a foreign serum such as that of the horse will prevent the persistent bleeding in these cases. If an extended trial of this method should confirm the mode of treatment a great step will have been taken in making operations possible in bleeders, whose condition at the present time is very sad. For sometimes such a patient will know that his tendency adds an enormous risk to a procedure which he must undergo, and his condition of mind, which serves as a factor in the decision as to the desirability of operating, becomes unfortunate. For the anxious, nervous patient will not stand a surgical treatment which in a stolid unimaginative man may be followed by complete success. Those who have had experience of lunatic asylums will probably agree that most of the inmates recover readily, even after severe operations, though some of the more acute cases bear operations badly.

The impairment of function by the removal of an excessive quantity of an organ will always tend to limit the activity of a surgeon in certain cases, but surgeons are unable at present to say what exactly are the limits of the possible in different directions. With one functioning kidney a healthy life can be passed, but whether life can be maintained with much less than one kidney has not yet been determined. We have somewhat more exact knowledge as to the extent of bowel which may be removed with impunity. The large intestine can be ablated completely and the patient seems to be none the worse; indeed, in some conditions the patient is much the better for the loss. Of the small intestine many cases are recorded where two or three feet have been excised without any noticeable impairment of function, but when the

amount of bowel removed exceeds this the result is not the same. Perhaps five or six feet may be excised without any marked effect, but even in these cases wasting to a greater or less extent may occur, while if more than this quantity be removed it is doubtful if life can be maintained for long. The power of absorption is so greatly diminished that sufficient material is not taken up from the shortened bowel. Recent progress in anæsthesia has rendered it possible for the surgeon to undertake operations which he would have looked at askance had only the older methods of preventing pain been available. Local anæsthesia has a great future before it, and the appreciation of the safety of very dilute solutions has justified surgeons in undertaking even extensive operations with its assistance. In this connexion may by mentioned Bier's method of producing ansesthesia in the extremities, and a paper by Mr. C. M. PAGE and Mr. S. G. MACDONALD describing this ingenious procedure will be found in another part of this issue (p. 1135). The production of extensive anæsthesia by means of the intraspinal injection of certain substances, such as stovaine and novocain, has opened a wide field of activity to the surgeon, and it is not improbable that improvements of technique will enhance its value greatly. Even at present the surgeon can operate in many cases in which the general condition of the patient would have otherwise gone far to negative any operative procedure. The developments in the facilities for operation are certainly large and getting larger, so that the surgeon of to-day must be on his guard against undertaking operations the just value of which, in gain to the patient in comfort and function, has not been estimated and balanced against the risk and the annoyance of the interference. The true extension of surgery is one thing, but it must not be forgotten that there are the things which ERICHSEN called "operative audacities," though the term would have been applied by him to procedures which are now so part of routine that the surgeon who did not carry them out, the right indications being present, would be a defaulter from ideal practice.

The Opening Addresses.

OLD customs die hard, and although half of the London schools of medicine dispensed with the time-honoured formal orations to usher in their present session, yet many schools continue to hold by the ancient observance. The "opening lecturer" can perform one of two functions. He can seize the rare opportunity of presenting to an intelligent section of the lay public the views of the medical profession, or of himself, upon some of the many urgent questions of the day which medicine can help the State to answer; in which case he will limit his remarks to the students whom he is nominally addressing to congratulations on the good sense they have shown in their choice of a profession and on their supreme discrimination in their selection of a school. On the other hand, he may make of the students his primary audience and offer them words of advice and encouragement concerning the study and practice of their future life-work; a discourse of this description may exhort the audience to industry in preparation or it may point to the results of

achievement. The opening addresses which our readers have had the recent opportunity of following have all been built up on one or other of these lines. Several of them contain much useful food for thought for the public, who should be interested in the maintenance of a high standard of medical education for those who are to have the future charge of its bodily welfare. Others have been primarily addressed to the student whom they have instructed in the methods of his training, often with special reference to its defects, whom they have advised as to the manner of work and attitude of mind which will enable him to carry out his education to his ultimate advantage, or whom they have encouraged by pointing either to the mountains of discovery which have been traversed by the medical heroes of the past or to the many misty peaks that still remain for conquest.

Turning to the addresses concerned more especially with medical education, our readers will have found Professor GEORGE MURRAY'S address to the students of Manchester unusually stimulating and instructive. Amongst many interesting points there especially come to mind Professor Murray's advocacy of conferences of medical teachers to ensure a better coördination between the many schools, and his remarks on the migration of students between different German universities, a system which has obvious advantages in imparting breadth of view, but which is counterbalanced, it seems to us, by considerations of convenience that render the adoption of a similar plan a difficult matter in our own country, unless it be by interchange of educational facilities between groups of the metropolitan schools, as was formerly the case. A broad outlook on medicine can be more readily given by postgraduate instruction at many centres, for which Professor MURRAY proved a strong advocate. He would have more practitioners follow the example of Cullen and William HUNTER, who when in partnership made an arrangement that each would alternately spend the winter in study whilst the other carried on the practice. Such a plan could, of course, only be adopted in the rarest instances nowadays, but there seems no reason why partners or even independent practitioners should not arrange with their colleagues to take their practice for a few weeks every third year whilst they took out a post-graduate course and renewed acquaintance with the atmosphere of medical research. Professor MURRAY'S remarks on the teaching of "clinical methods" and of clinical pathology were illustrated by certain American instances which our own teachers of these important subjects may do well to note, but at the same time he entered a plea for the formal lecture which has been abolished in the transatlantic schools and has been threatened with extinction in our own country, at least south of the Tweed. Professor MURRAY claimed that carefully planned and properly illustrated lecture courses may help the student with an imaginative faculty to acquire a power of mental visualisation over the processes of disease. A valuable suggestion was that in different schools certain groups of subjects should be studied systematically in the ward and the laboratory by men desiring to prepare their thesis for the doctorate. It is highly important that in the present inadequate state of endowment of medical research all

available facilities should be used to their utmost capacity and to a coordinated end, and we commend the suggestion to the authorities of the medical schools as worth a trial. No more striking instance could have been brought forward as showing the desirability of such a step than the unsatisfactory state of our knowledge of pneumonia, a disease which kills 40,000 people every year in England and Wales alone, and which some believe that HIPPOCRATES could treat as well as we can, even though he could not localise its seat. Of the few words on conduct which were addressed to the Manchester students we may repeat those which Professor MURRAY quoted from Professor MARX: "The best regulation for the medical profession consists in dignified humanity; this will prescribe in its simplest manner its relations to the State, to science, to the public.' Passing from Manchester to Liverpool we find Mr. C. A. BALLANCE addressing the medical faculty of the University and recommending to their attention the cultivation not only of humanity but of "the humanities," the study of books no less than of men. Medicine is not a thing apart from life; the two must ever be in the closest touch, and the physician is the man of all others who should hold nothing of human interest foreign to his own. Mr. BALLANCE did well to press home the need of general culture and knowledge of men to his student audience. His remarks on genius, on work, on play, and on attention will be found on another page of this issue of THE LANCET garnished with many gleanings from the storehouse of English letters, of which none is more inspiring than the stately address to PERSEUS which CHARLES KINGSLEY put in the mouth of PALLAS ATHENÉ.

At St. Mary's Hospital Dr. H. A. MIERS also gave his hearers some suggestions upon the methods of their study in an address which contained nothing of the conventional. He spoke of "Theories," and advised every student to formulate for himself a theory to explain every observed fact and not to abandon it until he was forced to revise it by the test of further knowledge. The advice is excellent for men of scientific honesty. If it is a little dangerous because some are too ready to find facts to fit their theories, yet we are constrained to bless it when we consider the overloading of the present course of medical study, and those facilities for the mental "spoon-feeding" of the student, to which others of the lecturers referred. The temptation must be strong for the student to acquire many facts without attempting to shape them into any useful edifice of thought, being content to bury the noble faculty of reason beneath the incubus of an artificially swollen memory. We cannot wonder that the Principal of the University of London deplored this tendency, for, as he told his student audience, he considers that men of their age should be in the most original, inventive, and creative stage of their existence. His exhortation to observation and research was thoughtfully expressed, and in speaking later of the inter-relationship of the medical sciences he could have held up no better example than the career of HELMHOLTZ. In this connexion we may direct attention to another opening address published in our present number, although delivered not at a medical school, but before the Medical Society of London, wherein Dr. SAMUEL WEST has some wery pertinent remarks to make on the mutual dependence

of the clinician, the physiologist, and the pathologist. Of the other addresses to students dealing with the means of preparation for the practice of medicine, Sir ISAMBARD OWEN at Bristol unfolded to his audience what may be called the university idea, concerning which no man has more authority to speak. One of his chief points was that the measure of success of a university is to be found not so much in the number of its graduates as in the amount of post-graduate work done within its walls. CLIFFORD ALLBUTT in his address at Charing Cross spoke in special praise of anatomy tempered by athletics, and told the wholesome truth that drudgery is a necessary condition of the proper acquirement of medical knowledge as of all other worth the having. At Middlesex Hospital Dr. J. S. GOODALL stood rather as the champion of physiology and made some courageous remarks about its teaching, with which we are in complete accord, but which can only be made effective by the goodwill of "intermediate" examiners. He passed in review the many stages of the medical student's education, and said this last word to the qualified man, "Don't make friends of your patients or patients of your friends," advice which few practitioners, we think, will be prepared to follow, though some might show good reason for doing so.

The remaining addresses were concerned with achievement. Dr. H. D. ROLLESTON at St. George's frankly took for his text "Let us now praise famous men," and a splendid roll he was able to call from the shades of HUNTER'S hospital. BRODIE, BAILLIE, THOMAS YOUNG, EDWARD JENNER were only a few of them, and a long list of those men of his school who rest from their labours he was able to add many names eminent in the living world of English medicine. At the Medical School of University College Hospital Sir JOHN TWEEDY surveyed the earlier achievements of medicine from the days of the Greeks and Alexandrians, through its dark ages down to the coming of the scientific conception of disease, which he showed was based on the experimental method and on that alone, and it is to be hoped that those of the general public who heard his address or read it in the newspapers will not forget his forcible lesson upon the need of continual research for the progress of knowledge and the advantage of humanity. At the London School of Medicine for Women Mrs. FAWCETT commemorated the work of the resolute women who opened the medical profession to their sisters this country, and showed forth the worth of the pioneer spirit, in whatever field it may be displayed. Yet another address, which also dealt with achieve ment, was delivered at Leeds, and we are tempted to award it the laurels of the October oratory. Although it came not from a medical man but from a judge of the Appeal Court, it showed an intimate understanding of certain great principles of health and disease which would have been amazing in a man whose researches have lain rather in civil than in natural law were it not for the knowledge of the methods and recent developments of curative science which Lord Justice Fletcher Moulton showed in his memorable vindication of their utility before the recent Royal Commission on Vivisection. No purpose will be gained by

summarising his address which we printed in full last week. Those who have not read it should know that they will find in it a statement of all the chief facts that have been certainly ascertained in the fields of bacteriological research and in the study of immunity, expressed in language of measured eloquence through which there breathes the true romance of scientific progress of which its speaker has clearly felt the thrill. We will recall one instance only of Lord Justice Moulton's powers of exposition, the passage in which he likens the man attacked with a sharp microbic invasion to a ship severely buffeted by the sea. The further she heels over, the stronger becomes the force of gravity known as the "righting couple," until she swings back once more to equilibrium. So in the human body attacked by a bacterial infection, the multiplication of the invading organisms calls forth Nature's own whip to scourge them, and the antibacterial forces of the body are generated in increasing quantity by the increasing violence of the bacterial attack. This is only the outline of the simile which was built up in a masterly manner in Lord Justice Moulton's address before he passed on to describe the methods of therapeutic inoculation by which our science and art can reinforce in many instances the natural defences of the body, and how this method of treatment has perhaps given us a weapon against the majority of diseases when its possibilities have been fully developed. In this account of the achievements of modern medicine given by a scientific judge we seem to read the fulfilment of the prophecy made 300 years ago by the greatest of English lawyers, the man who first opened the eyes of our own profession to the necessity of experiment for the advancement of their learning: "There is no doubt that if the physicians will learn and use the true approaches and avenues of Nature, they may assume as much as the poet saith :-

> ' Et quoniam variant morbi, variablemus artes : Mille mali species, mille salutis erunt.'''

The Employment of Patients with Arrested Tuberculosis.

THE crusade against tuberculosis is being carried on by both the profession and the public with an energy that is paralleled in the history of humanitarian movements only by the crusade against alcoholism. Every phase of the problem seems to have been discussed exhaustively over and over again. But there is one point which has not received adequate attention—the employment of patients whose tuberculosis has been arrested. In most cases the former employment is unsuitable because it has been a factor in the production of the disease; to return to it means to court a relapse. To abandon a calling in which skill has been acquired and learn another is difficult and entails pecuniary loss which few patients can bear. To join the overcrowded ranks of unskilled labour, where even the healthy often fail, is not more feasible. The prescription of a healthy open-air life is too often a counsel of perfection. If the patient is to follow it the employment must be provided for him. "Back to the land" is one of the remedies of the present-day reformer for the evil of unemployment. But farm colonies of the unemployed

are economically a failure. Would colonies of patients convalescent from tuberculosis not be a still greater failure?

In the Johns Hopkins Hospital Bulletin for August Dr. A. M. FORSTER publishes an article on the employment of patients with arrested tuberculosis which shows that the problem is not so hopeless as might be supposed. The difficulties in America are exactly the same as in this country. There many efforts are being made tocause the poor to migrate to the country. But lack of funds, ignorance and prejudice, lack of training in farm work, and the disagreeable aspects of country life all tend to retard progress. However, the convalescent consumptive who has left a sanatorium presents some differences from the ordinary city worker. He has been compelled for a time to give up his old conditions of life and been placed under a new discipline. Agricultural work, suited to his strength, will only be a continuation of the discipline—the discipline on which he knows his life depends. If the patient has been treated by graduated labour, which Dr. M. S. PATERSON has shown at the Frimley Sanatorium of the Brompton Hospital to be so beneficial, he can well undertake such work. There is one form of agriculture which the modern growth of urban life demands more and more, and which is particularly suitable for convalescent consumptives-market gardening. There is great room for its development in this country and in America, where both countries are behind the state of perfection to which market gardening has been brought in France and Japan. In many cases an entire family can live upon an acre of land. The work is not laborious, and as it is entirely open-air is very healthy. At the Eudowood Sanatorium, Towson, Maryland, of which Dr. FORSTER is superintendent, farm work has been carried on for three years with gratifying results. The system of graduated labour of Dr. Paterson was adopted-Some 50 acres of land in a very depleted condition were attached to the sanatorium. With the aid of the patients and two healthy negroes, who did the heavy work, operations were commenced. A barn and stable were built and a herd of cows added. In the second year the farm produced products of the value of 4000 dollars at a cost of 3400 dollars. Then an adjacent farm of 100 acres was added and a colony of ten. patients under the direction of a practical farmer was established. Of these men four had been tailors, one a shoemaker, one a moulder, one a blacksmith, and one a schoolboy. They formed a strange mixture of races—two native Americans, one Russian-Jew, one Pole, one Roumanian, three Irishmen, and two Germans. In five the disease had been apparently cured; in four moderately advanced and arrested; and in one far advanced and arrested. They all improved and it was found possible to pay them 10 dollars a month wages. Produce of the value of 6000 dollars was raised at a cost of 5000 dollars. Fruit trees were planted and not only was the sanatorium supplied with all its vegetables and milk but a large surplus of vegetables was sold. As a special advantage of the farm colony is that a tuberculous family can be placed on a farm to work without breaking home ties, we may find in this direction the solution of a very difficult

Annotations.

"Ne quid nimis."

THE ASSURANCE COMPANIES BILL AND INDUSTRIAL ASSURANCE.

It is much to be regretted that the Assurance Companies Bill, which has just left the Lords and is now awaiting an opportunity for consideration in the Commons, makes no attempt to deal with the serious evils connected with the present system of industrial insurance. The Bill, indeed, provides additional facilities for converting large collecting societies into industrial assurance companies; it, moreover, in Clause 36, proposes to enact that no policy, effected before the passing of the Act with any collecting society or industrial assurance company, shall be held to be void because the person effecting the policy had not at the time the policy was effected an insurable interest in the life of the person insured, if the person who took out the policy had at the time a bona-fide expectation that he would incur expenses in connexion with the death or funeral of the assured, and if the sum assured is not unreasonable for the purpose of covering such expenses. This provision was probably inserted in the Bill in the interest of present policy-holders, but its result would undoubtedly be to protect a large proportion of policies having their origin in the spirit of gambling, which is so serious a drawback to the present system of industrial insurance. It is much to be hoped that when this Bill is considered in the House of Commons some attempt will be made to deal with the undoubtedly difficult, but equally important, subject of insurable interest, especially with reference to the insurance of infants and young children. It was distinctly satisfactory to note that at the recent Trades Union Congress the subject of industrial insurance was discussed in a manner which proved that the members of trades unions are fully alive to the evils of the present system. The President of this Congress (Mr. D. J. Shackleton, M.P.) moved the following resolution :-

Having regard to the serious nature of the illegal practices connected with industrial insurance, which have led to widespread gambling in human lives, this Congress calls upon His Majesty's Government to institute an inquiry by means of a Royal Commission or a Committee with a view to legislation to prohibit such illegal practices.

Mr. Shackleton assured the Congress that its Parliamentary Committee would strenuously oppose the Assurance Companies Bill, then under consideration in the House of Lords, until some such inquiry had been held, as the facts of the case were too serious to be longer ignored. He asserted that it could be proved from the statements of insurance managers that fully 40 per cent. of the existing industrial policies were illegal. He claimed some consideration for those who were tempted by the insurance agents to take out policies, and who lost sight of the possibility of being unable to maintain the weekly payments; and also some protection for wives who were often persuaded to take out policies without their husband's knowledge. This resolution was naturally opposed by the representatives of the National Union of Assurance Agents, but on the ground that the Parliamentary Committee of the Congress was attacking a system and not individual agents the motion was approved and adopted. There can be no doubt that the proposed inquiry, in the interest of the industrial classes, should embrace consideration of the wasteful extravagance of the present system, under which the annual cost of commission to agents and the expenses of management are nearly equal to half the amount of the annual premiums, in spite of which most of the companies pay large a great extent the result of ignorance and neglect

industrial assurance offices and collecting societies shall in future report annually the number of lapsed policies, which involve heavy loss to the industrial classes and large profit to the companies and societies undertaking this class of assurance. Such an inquiry as was demanded by the recent Trades Union Congress is on many grounds urgently desirable. and there is now good ground for hoping that the Government may accede to this request of the Labour Members, who undoubtedly represent the opinions and wishes of the industrial classes on this subject and whose views are in accord with medical opinion.

A COLD SUMMER AND THE LOW DEATH-RATE.

THE mean temperature of the air at the Royal Observatory. Greenwich, was below the average for the corresponding period of 65 years on no fewer than 63 of the 91 days during the three months ending with September last. The mean temperature for this summer quarter did not exceed 58 · 7° F., and was 1.70 below the average temperature in 65 years. The mean temperature of the past summer was lower than that of the corresponding period in any year since the memorably cold summer of 1860. During last quarter 7.4 inches of rain were measured at Greenwich on 47 of the 91 days in the quarter, against an average of 5.8 inches on 33 days in the ten preceding summer quarters of 1899-1908. During the past summer the temperature was therefore exceptionally low and the rainfall was considerably above the average. It is satisfactory, but not surprising, to find that in accordance with previous experience the unseasonably low temperature and excessive rainfall during last quarter were conducive to a death-rate distinctly below the average. The mean annual rate of mortality during the 13 weeks of last quarter in the 76 largest English towns, with an estimated population of 16,445,281, did not exceed 11.9 per 1000, which is the lowest recorded rate in these towns in any previous summer quarter. This rate was, moreover, so much as 3.0 per 1000 below the mean rate in these towns in the summer quarters of the five previous years 1904-08, in which quarters the rate ranged from 17.5 in 1904 to 12.2 in 1907. The temperature and rainfall during the summer quarter of the year invariably exercise a controlling influence on the death-rate, more especially of infants, through the fatality of what is known as summer diarrhœa. The deaths of infants under one year of age in the 76 English towns during last quarter were equal to 120 per 1000 registered births, against 109 in the corresponding period in 1907, and 145 per 1000 in 1908. It is not easy to account for the excess of infant mortality in these towns during last quarter, compared with that recorded in the corresponding period in 1907, when the temperature was higher and the rainfall was exceptionally small. It is a fact, however, that the fatality of infantile diarrheea in the 76 towns was greater during last quarter than in the same period of 1907, although it was considerably below the average fatality in recent summer quarters. The mean annual death-rate from the principal epidemic diseases in the 76 towns during last quarter was equal to 1.60 per 1000, against 1.47 and 2.35 in the corresponding periods of 1907 and 1908. The death-rate from these diseases in the summer quarter of the year, as well as the rate of infant mortality, are mainly governed by the fatality of diarrhoea, more especially in urban populations. Thus, of the 6557 deaths referred to the principal epidemic diseases in the 76 towns during last quarter, 3976 were attributed to diarrhœa, against 2335 and 6929 respectively in the corresponding quarters of 1907 and 1908. The fatality of infantile diarrhoea is to dividends. It should, moreover, be enacted that all in the treatment of infants, and in view of the

recently increasing efforts of local authorities to combat this ignorance and neglect, it is disappointing to find that, under meteorological conditions exceptionally favourable, the death-rate from this cause last quarter should have considerably exceeded the rate recorded in the corresponding period of 1907, although the death-rate from all causes was lower. The forthcoming Registrar-General's return relating to the past quarter will presumably show the usual wide variations among the several towns in the fatality of diarrhea and in the rate of infant mortality. The causes of these variations have never yet been fully and satisfactorily explained, although they obviously point to corresponding variations in the care and treatment of the infants.

"THE DAY OF SMALL THINGS."

Dr. May Thorne delivered the inaugural address at the fifth annual public meeting of the Association of Women Pharmacists at the premises of the Pharmaceutical Society on Oct. 8th, taking for her text "The Power of Little Things." She first illustrated it from the realm of Medicine, showing what havoc has been, and is being, wrought in the human race by the tubercle bacillus, one of the least of all little things, and how a constant attention to methods of healthy living, which some people are tempted to consider of small importance, is our chief safeguard against the unseen but deadly attack. Her next example was the plague, which was at one time thought to be due to the presence of infected rats, whereas now the rats are believed to be free from the disease themselves but to be the carriers of fleas, which, although no human eye can see them without powerful aid, are able to harbour and spread broadcast the seeds of a terrible infection. Other well-recognised examples were mentioned to show how small insects such as flies and mosquitoes play an important part in the dissemination of disease, and that where the beasts of prey, for all their ill-repute, kill their units, fleas and flies kill their thousands, whilst micro-organisms destroy millions of human lives Other examples of the power of little things were drawn from chemistry, which teaches that by the addition of a molecule the whole character of a substance may be changed, and then Dr. Thorne brought her subject home to her audience by reminding them of what grave issues might arise from the smallest seeming slip in dispensing or writing a prescription. To those who were starting their career in pharmacy Dr. Thorne urged that it is the little things which are often the powerful factors for future good, and lastly, she recalled the word of the Lord which came unto Zechariah the prophet, "For who hath despised the day of small things?"

AN EARLY DEVELOPMENT OF THE GERM THEORY OF DISEASE.

WE have received an interesting communication from Dr. P. Fusco of Rome, who desires to call the attention of the present generation of English medical men to the views on the germinal origin of infective diseases which were held by the late distinguished physiologist Dr. Lionel Beale, who was without doubt one of the most brilliant microscopists that this country has known. In reading Beale's work on "Disease Germs, their Nature and Origin" 1 Dr. Fusco has been much struck by its author's apparent prevision of the most modern conceptions of bacterial disease, a science which at the time of his writing the book was, of course, in its infancy. It is true that nearly ten years before Davaine had suggested the filiform bodies occurring in the blood of animals suffering from anthrax to be the

cause of that disease, but it was not until five years later that Pasteur started his investigations on the subject, under the impetus of Koch's experiments and of his own discoveries in connexion with silkworm disease. It is, indeed, somewhat surprising that the following passage which Dr. Fusco quotes from Beale's book has escaped the recognition of modern bacteriologists: "Some forms of disease germs not only 'protect' the organism from a second invasion of the same kind of germ, but the change induced is a sufficient 'protection' against allied forms. And there is indeed reason to hope that means may be discovered. perhaps by passing it through the bodies of animals, or in some other way, of rendering the poison milder, without destroying its efficacy as a protecting agent—in fact, that we may produce a mild and harmless disease, in order to 'protect' the organism from the chance of suffering and being destroyed by a most virulent and very fatal form of the same malady. We may feel sure, not only that this is possible, but that it will be done. In this direction our work should be unremitting" (loc. out., pp. 227-28). This is indeed a remarkable passage, seeing that Pasteur's experiments on the attenuation of the virus of anthrax and chicken cholera were not made until five years after its publication and the formal announcement of the microbic theory of disease was not made by the great Frenchman in the names of Joubet, Chamberland, and himself until the spring of 1878. In reading the work we have come across other passages no less worthy of notice. On p. 176 we find, "No investigation is likely to be more fruitful in valuable results than a very careful inquiry into the microscopical and chemical characters of the blood just before its invasion by contagious diseases germs, and the alterations effected by them during the period of incubation. There is muchreason to think that certain states of the blood are favourable to the multiplication of the poison, while others, perhaps, render its destruction almost certain." This is so accurate an epitome of our present conception of immunity that its enunciation nearly forty years ago on inductive principles may almost be called a scientific inspiration. But Dr. Beale's book did not confine itself to speculations on the future. He wrote some very practical advice concerning the spread of contagion by infected water, giving directions for its sterilisation and on the desirability of keeping surgical patients and lying-in women separate from cases of infective disease. His remarks on the contagion of syphilis are also most interesting in the light of our recent knowledge. How comes it, then, that his claims to be a pioneer of bacteriology have been so long neglected? The answer lies in the very book from which we have quoted. He was unable to believe that vegetuble bacteria, the minute fungi which he well knew to exist, were the true cause of infective disease. Those who desire to know hisreasons for this opinion will find them on pp. 78 to 84 of the book in question, and we will content ourselves with repeating his conclusion that "the vegetable organisms when present (i.e., bacteria and micrococci)are but accidental concomitants and that a potent poison, not of the nature of a vegetable germ, is present in the animal fluid or solid in which the contagious properties are known to reside." What, then, were the germs which Dr. Beale believed to be the contagious particles of disease? The greater part of his book is devoted to their description. He considered them to be animal "germinal particles" of bioplasm, the living or self-propagating matter of living beings which had undergone a form of degradation, but in doing so had acquired toxic properties and a power of almost indefinite multiplication. He made a bold speculation that their ultimate source was in a human body, that they were in fact originally derived from diseased and degenerated

leucocytes which Dr. Beale considered to be the bioplasm of the blood; but whatever their origin might have been he was convinced of their existence and gives many figures in his book to illustrate their microscopical appearance. As to what were these bodies which he undoubtedly saw we cannot now speculate, but it seems probable that his small blood bioplasts were what we now know as blood platelets. The size of these "animal germs" he put down as 1/100000 of an inch, about $\frac{1}{4}$ μ , and, of course, much smaller than the vegetable bacteria; and he was convinced that these living germs of disease did not arise in the body de novo, whatever may have been their ultimate origin, but were introduced from without. Of their properties he gives the following description, which can be applied with astonishing accuracy to the vegetable bacteria in which he was unable to believe as the true materies morbi: "The contagious virus is living and growing matter: the particles are not directly descended from any form of germinal matter or bioplasm of the infected animal, but they have resulted from the multiplication of particles introduced from without and capable of growing and multiplying in the blood: the particles are so minute that they readily pass through the walls of the capillaries, and multiply freely in the interstices between the tissue elements or epithelial cells: they live and grow at the expense of the various tissue elements." We consider that these sentences alone should rescue Dr. Beale's name from bacteriological oblivion. They were largely the outcome of pure reasoning, and it must be remembered that when this doctrine of the germinal bioplastic cause of disease, which he applied to all the infective fevers, to syphilis, tubercle, and in some sort to cancer, was put forward to refute the theory of the vegetable bacteria none of the cultural and inoculation experiments which resulted in the confirmation of the latter conception of disease had yet been performed. We should like to give further consideration to the many ideas contained in this forgotten volume, but have perhaps quoted enough to introduce it to the notice of those who are interested in the evolution of modern medicine and to recall to memory an original and brilliant thinker who was known to not a few of our readers.

SUNLIGHT IN A TEST-TUBE.

In 1774 a theologian, described as of an eccentric, restless, fiery nature, turned the rays of the sun by means of a magnifying glass upon some red precipitate imprisoned over mercury in a tube. His curiosity was rewarded after a while by the appearance of bubbles of gas, and Joseph Priestley had discovered oxygen. The importance of the discovery to medicine amongst other sciences was, of course, very great. About 120 years later physicists calculated that the heat received by the earth under a high sun and clear sky was equivalent to about 7000 horse-power per acre, but until recently nobody has got a step farther than did Priestley towards utilising this energy for practical purposes. It has been suggested, however, that some day our centres of industrial activity may be transferred to the burning deserts of the Sahara and the value of land determined by its suitability for the reception of traps to catch sunbeams. The practical utilisation of the sun's influence is certainly of far greater concern to the human race than, for instance, aviation. The conquest of the air, like that of the sea, must be dependent upon our supply of energy. Fuel, in the shape of coal and petroleum, is the chief source of energy at the present time, but it is utilised in a clumsy and extravagant way. The tides and waterfalls will no doubt in time be made to do their share, but even the energy of these is insignificant compared

with the enormous energy received from the sun. Is the notion of utilising this energy too chimerical for serious consideration? In face of the measures of success already gained in regard to securing and controlling natura) forces it would surely be over-timid to answer this question in the affirmative. Further, although the investigation of the subject does not hold out the promise of the "sporting time" which experimental aviation appears to give, yet there is a band of busy workers giving keen attention to it. Any day the startling announcement may come that human ingenuity has succeeded in boiling the kettle with but a few minutes' exposure to the accumulated energy of the sun's rays. A bottle of water may set the house on fire just as a pipe may be lighted by means of a glass lens. A comparatively simple experiment, but of great significance, has recently been performed which may mark the beginning of a series of wonderful practical achievements in this direction. It has been shown that by focussing the sun's rays on some crystalline silicon contained in a vacuum in a glass vessel the crystals fused in a few seconds, showing that a temperature of 1450°C. had been obtained. In a similar experiment copper and cast-iron were fused almost instantaneously. The success of the experiments appeared to depend upon the fact that the substances were contained in vessels emptied of air, for on admitting air the temperature did not exceed 675°C. From the test-tube to the steam boiler, the dynamo, and the electric cell is but a step, and Priestley's classic experiment of 1774 may receive a fame not yet reached by any other laboratory success.

THE UTILITY OF EXAMINATION OF THE NOSE AND NASAL SECRETIONS FOR THE DETECTION OF LEPROSY.

Stricker some years ago asserted that the initial lesion of leprosy was a specific ulceration of the cartilaginous septum of the nose, and in view of the fact that the bacillus lepræ is frequently found in the nasal discharges of leprous patients other observers adopted Stricker's opinion. Among these supporters we may mention Dr. Victor Heiser, Director of Health for the Philippine Islands, who in a recently published paper stated that the earliest and most constant symptom observed in the Philippine cases was an ulcer situated on the nasal septum. Among 1200 cases of leprosy taken in sequence at the leper station on the island of Culion he found these ulcers noted in no fewer than 799; and he adds that probably, if very careful and special examination had been made in the other cases, some trace, such as scar tissue, would have been discovered and would have furnished presumptive evidence that ulcers on that site had previously existed. His experience of the examination of a large number of lepers in the Philippines and elsewhere confirms his view of the importance and constancy of this sign, which may be often found, he says, long before there are any other objective or conscious subjective symptoms of the disease. With the object of determining, if possible, whether the views of Stricker and his supporters could be confirmed, and, if so, whether they could be made the basis of some practicable procedure for the detection of incipient leprosy cases, some valuable and interesting researches have lately been made by Dr. Walter R. Brinckerhoff, director of the Leprosy Investigation Station for the Hawaiian Islands, and Dr. W. L. Moore of Honolulu. The results of this inquiry have been recently published in pamphlet form as No. 4 of "Studies upon Leprosy," under the authority of the Government of the United States. The report was also communicated to the Conference on Leprosy held at Bergen in August last. These two observers set themselves the task of finding out whether the

systematic inspection of the nasal septum and the bacteriological examination of the nasal secretions of a large number of individuals belonging to a race known to be susceptible to leprosy would reveal early cases of the disease which would pass undetected by other ordinary methods of investigation; and whether, when an early case of leprosy is under observation it could be said that the malady could have been discovered by examination of the nasal septum and the nasal secretions alone. For this purpose the investigators inspected the nasal septum and examined bacteriologically the nasal discharges of upwards of 700 persons, 400 of them native Hawaiians, and some of them the children of leprous parents, living in seven public institutions. They also examined a number of patients who were attending the Free Dispensary and the Public Hospital at Honolulu. Dr. Brinckerhoff and his colleague admit that the majority of those examined were living in public institutions under good hygienic conditions which were unlikely to foster the infection of leprosy; and, moreover, most of them were constantly under some sort of medical supervision, which would probably have detected any of the early manifestations of the disease. The two investigators as a result of their inquiry, so far as it went, formed the opinion that many nasal lesions seen in lepers are of a non-specific character and have no diagnostic value. They also came to the conclusion that no considerable number of individuals in Hawaiian institutions have, as the sole evidence of leprosy, lesions in the nose which are discharging the bacillus lepræ. They therefore feel justified in doubting the value of nasal examination for the discovery of incipient cases of the disease. At the same time they admit that the specific microbe is very frequently found in the nasal discharges of lepers, and the importance of this fact from the prophylactic point of view cannot be too strongly insisted upon; but they point out that in such cases the disease has existed for some time, and they conclude that the existence of nasal ulcers has not necessarily any significance in determining the site of the initial lesion. They do not therefore recommend "wholesale" nasal examinations as a certain means of detecting early cases of leprosy, but they express the opinion that in "clinics" frequented by races which have a high incidence of leprous infection it is advisable that thorough inspection of the nasal septum should form part of the routine examination of all persons applying for medical advice.

BOY AND GIRL LABOUR.

THE question of child labour is one of the greatest importance: first, as regards the health and physique of those who will be the fathers and mothers of the coming generation; and secondly, as regards matters of social economy, for child labour is a fruitful source of production of the loafer and the wastrel in both sexes. An interesting little pamphlet has been issued on the subject by the Women's Industrial Council, written by N. Adler and R. H. Tawney, in which the problem is discussed with a sanity and restraint which are rare among the mass of writings on social reform which are daily poured forth. The authors point out what is well known, that child labour is a prominent cause of unemployment, and, worse, of "unemployability," if we may coin a word. Besides, child labour, especially in the case of boys, tends "to set no end for attainment before the boy, and therefore supplies him with no motive to steadiness and self-improvement." The decline of the apprenticeship system is noted, but as the authors truly say "the real problem of the juvenile worker with which society is faced to-day is not the apprentice at

industrial training is, even ostensibly, conceded." The kind of employment to which too many boy and girl workers are put is stigmatised by the term, "blind alley occupations." Such occupations are, of course, due to two main factors, the one the modern system of division of labour, and the other the stress of modern competition and the natural desire of employers to obtain their labour in the cheapest way. It is far more paying to hire relays of boys to label bottles or to pack soap all day long than to give them any training which will enable them either to move up to a higher position in the same factory, or to find other work in a different one, on attaining the age of 18 years or so. They have learned to do nothing else, and when they ask for men's wages they are dismissed and their places taken by other boys. In this way the unskilled labour market is constantly being filled up. With regard to remedies, the authors divide their suggestions into two classes, legislative reforms and administrative reforms. The former include a series of Acts of Parliament which would firstly abolish the half-time system under 14 years of age as soon as possible and ultimately under 15 years; secondly, would prolong fulltime education up to the age of 15 years; and thirdly, would halve the present hours of labour among boys under the age of 18 years, so that they might use the time thus gained for continued education under a new and improved half-time system. The administrative reforms chiefly deal with the question of the regulation, and, if possible, the abolition, of street-trading for children under the age of 16 years, and the furtherance of attendance at evening classes. In the matter of girl labour, the authors advocate the establishment of more trade schools on the model of the Écoles Municipales Professionnelles such as exist in Paris and other French cities. At present there are 530 girls under trade school teaching in London as against nearly 2000 in Paris. Girls who wish to work later at a skilled trade should be enabled to spend one year at some trade school on leaving the elementary schools. Further, girls who intend to take up unskilled employment or domestic service should be obliged to attend a half-time continuation school for the teaching of such matters as needlework, cookery, and dressmaking. The above-mentioned suggestions seem to us to be well worthy of consideration by our legislators, although we do not assume that they should necessarily be carried out in the absolute form in which they are presented in the pamphlet. But that they form a solid ground-work for muchneeded reforms is indisputable, and we commend the pamphlet to all interested in the question. And no section of the community is more practically interested in "unemployability" than medical men, who see its miserable physical and moral results so close at hand.

[OCT. 16, 1909.

· THE WASSERMANN REACTION IN CARDIAC DISEASE.

THE sero-diagnosis of syphilis devised by Wassermann is proving its value, not merely as an index of syphilitic infection in individual cases, but also as an important witness to the syphilitic nature of certain lesions and maladies whose etiology is still under discussion. The most notable example of this application of the test is seen in the experiments which in various hands have established more firmly than before the importance of syphilis in the production of tabes dorsalis and general paralysis of the insane; and the almost equally vexed question of the importance of syphilis in the production of aortic disease receives new light from the investigators who have applied the serum test to the elucidation of this problem. Chiari's researches showed that in a large proportion of syphilitic persons examined post mortem a productive meso-aortitis was to all, but the boy and girl to whom no opportunity for be found by microscopic investigation. The further

question, answered in part by the researches of Citron 1 and Collins and Sachs,2 is the proportion of all cases of aortic disease attributable to syphilis. The former writer, testing cases of aortic regurgitation by the Wassermann reaction, gained positive results in over 60 per cent., in a proportion larger than that of a history of syphilis. two American physicians using the test in its classic form with liberal controls examined 36 cases in all—cases of aortic insufficiency, aneurysm, congenital cardiac malformation, mitral stenosis, arterio-sclerosis, angina pectoris, and other cardiac disorders. In their five cases of aneurysm they found a positive reaction without exception. There were 13 cases of valvular disease implicating the aortic valves only; in 12 of these the reaction was positive, in 10 pronouncedly so. In five cases the aortic lesion was complicated by disease of the mitral valve; in this group there was one positive reaction with two weakly positive and two negative reactions. In 11 cases of uncomplicated mitral disease a positive reaction was found twice only. From these findings the authors conclude that syphilis is an important factor in the production of cardiac disease, and that it is specially concerned with the genesis of lesions of the aorta and its valves. Here, indeed, syphilis is in all probability the most important exciting cause. The value of the test in its application to individual cases is illustrated by several examples described in detail, and it is interesting to note that only 11 of the 24 patients who reacted positively to the test gave a history of venereal disease.

THE METROPOLITAN WATER-SUPPLY.

THE Water Examiner has issued his report on the condition of the metropolitan water-supply during the month of July, 1909. The mean rainfall for the month, calculated as representing all parts of the Thames basin, was 2.95 inches, being 0.66 of an inch above the average for that month during the previous 26 years. During July the average daily natural flow of the Thames at Teddington Weir was 684 · 6 million gallons, being 141.4 million gallons above the average for the 26 preceding years. The Thames water at Hampton, Molesey, and Sunbury was in good condition during the whole of the month. Dr. A. C. Houston, the director of water examinations of the Metropolitan Board, has made a large number of exhaustive analyses of samples of water from the various sources of supply of the metropolitan area. These comprise chemical analyses of 63 samples of raw river water and of 183 samples of filtered water, also bacteriological analyses of 63 samples of raw water and of 552 samples of filtered water. The details of the analyses and the report as to the conclusions to be drawn are contained in the report by Dr. Houston which is appended. The chemical results showed for filtered waters a very slight deterioration and for the raw waters somewhat less favourable results than for the corresponding period in 1908. The deterioration is evidenced especially by the results of the albuminoid nitrogen test and the test depending on the oxygen absorbed from permanganate. The bacteriological results show that the three raw waters contain fewer bacteria than the average for this period, but the filtered waters often contained an excessive number of bacteria. It is reassuring to learn that the tests for the presence of the bacillus coli are satisfactory for both the raw and filtered waters and compare favourably with the corresponding period for last year. The filtered waters were tested as regards the presence of the bacillus coli in 100 cubic centimetres, and the percentage of negative results for each water is tabulated. A first-class water unpolluted with any sewage

or excremental matter would give 100 per cent. of negative results for the various tests made for the bacilluscoli. None of the filtered waters reach this high standard. The East London (Lee), East London (Thames), and the Rye Common waters give in this order the worst results as regards the presence of the bacillus coli. Dr. Houston is continuing his investigations on the effects of storage of water antecedent to filtration, and the results for July confirm those of previous months as to the very valuable benefit derived from this simple process. The words of his June report are applicable to July—viz.: "It is an underestimate of the actual truth to assert that (at present) a large proportion of the water now being delivered on to the London filter-beds is rendered at least 100 times less impure (bacteriologically), as the result of storage, than the raw river water."

OCULAR THERAPY IN GERMANY.

WE have received several numbers of a journal entitled La Clinique Ophtalmologique, the articles in which are chiefly devoted to therapeutical investigations. Some of these are worthy of special notice. The journal is published in Paris under the editorship of Dr. R. Jocqs, Dr. A. Darier, and Dr. L. Dor. A good idea of the present state of oculartherapeutics in Germany is given by Dr. Darier, who remarks that in that country it is held that the surgeon ought to have some slight knowledge of the diseases of the eye and know when to call in the services of a specialist, as in all cases of septic infections of the cornea, of penetrating wounds, as well as of those in which vision is compromised, where an operation is called for, and where after treatment the question of indemnity is likely to arise. The practitioner who is first called in ought to be able to ascertain the conditions that are present, and to give his reasons for active measures, which may be of great service in the subsequent history of the case, but he should not undertake alonethe responsibility of the after-treatment. Care should be taken that patients suffering from infectious disease, such as gonorrhœal or diphtheritic ophthalmia or acute epidemic conjunctivitis, should not touch their eyes, and that all handkerchiefs, towels, and cloths used by them should be purified. General hygiene and dietetics should be attended to, patients should avoid all violent efforts that may cause congestion of the head, should abstain from excess in alcohol andcoffee, and from mental strain and cold feet, while arrest of the catamenia should be avoided. Diabetes and gout should be treated secundum artem. The urine should be frequently and carefully examined. Moderate action of the bowels should be secured, especially if there be much indican in the urine; personal cleanliness should be enjoined, but hot baths and sudorifics, formerly much recommended, are apt to fatigue. Hot drinks and salicylates are of much service in iritis, choroiditis, and neuritis. Saline baths are often beneficial, especially in those affected with scrofula, and sea air often proves useful. In infectious diseases of the lids topical antiseptic remedies are used, such as solutions of silver nitrate and protargol, and Dr. Darier remarks that the remedy he himself was the first to introduce, argyrol, might well be mentioned. Sulphate of zinc is the sole remedy that seems to have a specific action on the diplo-bacillus. Infections of the globe of the eye are less accessible to antiseptics, the employment of the galvano-cautery being the most efficacious. The intra-ocular application of iodoform is considered very questionable. Serotherapy has been tried in different affections due to specific microbes, but the normal aqueous humour takes up very little antibody and the vitreous humour practically none at all. Ocular diphtheria is almost the only affection which has really benefited by serotherapy. Neither the antipneumococcic serum nor the antistreptococcic

Berliner Klinische Wochenschrift, 1908, No. 48.
 American Journal of the Medical Sciences, September, 1909.

has given very satisfactory results. These remedies, however, may, Dr. Darier thinks, exert a paraspecific actionthat is, without being infallible per se, they may prove of great service when combined with topical remedies. The tuberculin of Koch is in very frequent use, primarily from a diagnostic point of view. A milligramme of the old tuberculin injected under the skin produces a general and sometimes a local reaction. If it fails to do so a fresh dose of 5 or perhaps of 10 milligrammes is injected. When once the diagnosis is established the treatment with tuberculin T.R. may be commenced with 1-500th of a milligramme, and be continued with progressive increase in the strength of the dose. Augmentation of the antibodies and of the leucocytes is thus induced. In the contest with ocular infections, in addition to preparations of salicylic acid, there are the methods of mercurial medication, effected by internal administration, friction on the skin, and hypodermic and intravenous injections. Exceptional care should be taken in the administration of mercury in tabetic patients. Preparations of iodine are frequently prescribed, especially in affections of the optic nerve and of the motor nerves, in rheumatism of the uvea and of the sclerotic, in diseases of the vessels, and in hæmorrhages. From 10 to 20 grammes are dissolved in 300 grammes of water and a dessertspoonful is taken in soup or in milk. Hypodermically iodipin is employed. Sometimes large doses, as 10 grammes per diem, will act when smaller doses fail. It will be remembered that calomel insufflation must not be practised whilst preparations of iodine are used. The beneficial effects of various remedies can be intensified by heat, by massage, and by subconjunctival injection. Solutions of from 2 to 4 per cent. of common salt are employed after cocainisation or the instillation of acoine in septic keratitis and parenchymatous keratitis when on the decline. They are not appropriate in cases of iritis Guaiacol, salicylate of sodium, and sodium iodide may be employed. Salicylates and aspirin have replaced opiates; nevertheless morphia proves serviceable in glaucoma not only by soothing pain but from its action as a myotic. Potassium bromide, veronal in doses of 0.5 to 1 gramme, and trional in 1 gramme doses have been effective in relieving pain. Cocaine retains its position as an analgesic but may be replaced by holocaine, eucaine, and dionine, but their action is briefer. Acoine in \(\frac{1}{2} \) per cent. solution renders subconjunctival injections painless. The practical nature of the information in this article is well displayed by the excerpts we have made.

THE MEDICAL INSURANCE COMMITTEE.

A MERTING of the Medical Insurance Committee was held at the offices of the British Medical Association on Thursday, Oct. 7th, when the best means of bringing the advantages of the scheme before the medical profession were discussed, and a considerable advance in business was also announced. Dr. G. E. Haslip was elected chairman of the committee in place of the late Dr. H. Radcliffe Crocker, on the motion of Dr. Dawson Williams, which was seconded by Dr. Squire Sprigge. The following resolution was then unanimously adopted :-

That the members of the Medical Insurance Committee desire to convey to Mrs. Radeliffs Crocker their sincers sympathy in her bereavement, and their sense of the loss they have sustained by the untimely death of their colleague, Dr. Radeliffs Crocker, who had acted as chairman of the Medical Insurance Committee since its formation. The members of the committee recognise that it was largely owing to his keen interest and business aptitude that it has been possible for the committee to work up so large a business.

Mr. Guy Elliston, General Secretary of the British Medical Association, who is the agent and secretary of the committee, then reported that there was a policy issued at Lloyds for insuring the motor-cars of medical men upon specially reon p. 1163 of this issue of THE LANCET, and we have much pleasure in recommending it to the favourable consideration of our readers. It is a source of gratification to us that the work of the Medical Insurance Committee continues to progress steadily, and we look forward to the time when, owing to increase of business, the committee will be able not only to offer the same substantial rebates to insurers but to carry over a surplus by which some selected medical charity or charities will be benefited.

PAINLESS DENTAL DISEASE AS A CAUSE OF NEURASTHENIA AND INSANITY.

THE multiplicity of causal factors to which the development of neurasthenia and of insanity is attributed is an indication of our ignorance on the subject. That cause and effect are integrally related is axiomatic, but when the same effect apparently is produced by a variety of causes we begin to doubt the genuineness of the latter, and feel that we have not advanced far in the matter of etiology. It has long been known that irregular teeth are common in the insane and among habitual criminals, as well as in the epileptic. but hitherto it seems that there has been no attempt to establish or to disprove a causal connexion between dental affections and nervous and mental diseases. Irregularity of the teeth has been regarded as one of the stigmata of degeneration, a group of anatomical and physiological peculiarities which is constantly being added to in a curiously unscientific way, and they have usually been considered as the outward expression of some unknown constitutional tare. It has remained for Dr. Henry S. Upson, professor of neurology in the Western Reserve Medical School of Cleveland, to suggest that dental trouble may be the actual cause of certain cases of neurasthenia and insanity. In the Cleveland Medical Journal for August he adduces interesting, if not altogether convincing, facts in support of his somewhat novel views. One, of the simplest dental lesions is impaction. When a tooth is formed in the maxilla with its axis wrongly directed it is often prevented by impaction against another tooth from appearing outside the bone or through the gum. The result in some instances is severe toothache or neuralgia, but in most cases no such pain is present. Systematic examination with the help of the X rays of a large number of patients in three of the State hospitals revealed a considerable number of cases of impaction among patients suffering from one or other of the psychoses. Prompt recovery from insomnia and melancholia after the relief of dental lesions in a few led Dr. Upson to prosecute his inquiry more widely, and in his paper he records numbers of cases in which definite nervous and mental symptoms vanished at varying intervals after a visit to the dentist. A series of excellent X-ray photographs illustrates the type of dental affection-impaction, the removal of which seems to have been followed by such beneficial results. cannot doubt the reality of the improvement achieved, although it is permissible to question the accuracy of the nervous or mental diagnosis in some instances. Further, when we consider the extent of our actual knowledge, such a statement as "of all cases of neurasthenia and the psychoses, not due to obvious physical causes, such as digestive disorders and eye-strain, the great majority, possibly four fifths in men and three-fifths in women, are due to dental diseases," is a little too sanguine, even when we admit the enthusiasm of a worker in a new field of research. The phenomenon of reflex irritation is accountable for much in nervous symptomatology, and no therapeusis is sufficient which ignores obvious sources of irritation, such as adenoids, dental caries, balanitis and preputial adhesions, aural mischief, astigmatism, and so on; but Dr. Upson maintains that impacmunerative terms. A synopsis of this scheme will be found | tion commonly occurs without any symptom, in particular

without pain, and yet we are asked to recognise it as a cause vera of dementia præcox, melancholia, manic-depressive insanity, neurasthenia, the psychoses, and what not. Of course, in many dental affections pain may be the exception, though reflex irritation may all the time be at work, but as a rule the latter shows itself in local reactions merely, such as facial neuralgia, and more generally as headache and sleeplessness. Whether to its action more profound dis turbances are to be attributed remains to be seen, and Dr. Upson is himself conscious of the need for further investigation ere the evidence be deemed conclusive.

POISONING BY ATOXYL.

In order to throw some light upon the toxic effects which sometimes occur in man as a result of the use of atoxyl Dr. J. Igersheimer and Dr. Itami have carried out a series of experiments in the Pathological Institute of the University of Heidelberg, and have recorded their results in an interesting paper published in the Archiv für Experimentelle Pathologie und Pharmakologie, Vol. LXI., p. 18. They find that both with acute and chronic poisoning in dogs severe hæmorrhage into the kidney occurred almost invariably. This they maintain is the result of a primary effect upon the circulatory mechanism of the kidney and not, as some observers state, due to a hæmorrhagic nephritis The hæmorrhage occurs between the cortex and medulla and leads to a more or less extensive atrophy of the parenchyma of the organ. In the cat in subscute or chronic poisoning a train of nervous symptoms are set up consisting in slowness of movement, ataxy, clonic twitchings, and more or less severe spasms and spastic paralyses. The changes underlying these symptoms are found to have their situation in the central nervous system, consisting in severe degenerative processes in the cells of the brain and spinal cord. In both cats and dogs the ordinary symptoms associated with poisoning by inorganic arsenical compounds may be present in addition-viz., inflammation of mucous membranes, conjunctivitis, and trophic changes in the skin. Further experiments with other organic arsenic compounds seemed to indicate that the symptoms of poisoning by atoxyl are not confined to atoxyl alone, but may occur with other aromatic arsenical compounds. By subacute poisoning with atoxyl no change in the blood picture is made other than a moderate anæmia. The experiments gave no support to the view that the action of atoxyl is due to its anilin or phenyl component. The ocular changes which are produced by atoxyl are to be made the subject of a further paper by Dr. Igersheimer.

THE EARLY TREATMENT OF THE INSANE IN THE COUNTY OF LONDON.

THE proposals of the Asylums Committee of the London County Council for the establishment of receiving houses for the reception of cases of incipient insanity, already published in these columns,1 were considered by the Council on Oct. 12th at the first meeting after the summer recess. The committee recommended, after going fully into the subject, "That application be made to Parliament in the session of 1910 for powers to enable the council to establish and maintain receiving houses for alleged lunatics in the County of London." To this an amendment had been put down by Mr. Hayes Fisher on behalf of the Finance Committee to omit the words "receiving houses" and insert "as an experiment a receiving house." Mr. Hayes Fisher being absent through illness, Sir George Goldie moved on his behalf, but omitted the phrase "as an experiment." While not professing to be an expert on the question he urged the amendment on

general grounds of economy and advisability. A. F. Buxton seconded, arguing that it might be easier to get the Bill through if powers were only asked for one receiving house. Mr. Evan Spicer, however, pointed out that by getting full powers the council did not pledge itself in any way as to the number of receiving houses, It seemed a great piece of extravagance on the part of the Finance Committee to suggest that heavy Parliamentary expenses should be incurred twice if the experiment was successful. Sir John M'Dougall urged that one receiving house for the whole of London would be worse than useless. The object was to close the lunacy wards of workhouses, but one receiving house could not have that effect. so the present expenditure would still go on side by side with the new. The experiment under those conditions would be doomed to failure. What district would one house serve? A receiving house in the east would not serve the west, and he thought that there should be at least four. Mr. Ernest Gray asked, if the experiment was a failure, would any council add to the number of houses? If, on the other hand, the experiment was a success the amendment simply delayed the accomplishment of a reform which everybody desired. Mr. E. White thought that the council should be satisfied with one receiving house, and there would be no difficulty in inserting a clause in the Annual General Powers Bill to extend the scheme if necessary. Mr. Sidney Webb retorted that further powers could not be obtained without a special Act of Parliament, as an amendment of the lunacy laws would be necessary. To go to Parliament twice when once would do would be absolutely unnecessary expenditure and "a mere wanton, wicked waste of money." On a show of hands there voted: for the amendment, 29; against, 34. A division resulted, however, in 45 votes being cast for the amendment and 44 against. An appeal that the debate might be adjourned for further consideration was disregarded and the question as amended was then carried.

THE VIRTUES OF THE ULTRA-VIOLET RAYS.

THERE can be little doubt that the ultra-violet rays are the friend of man in many ways. A series of carefully conducted researches has already shown that it is the ultraviolet rays in sunlight which are responsible for the production of ozone in the air, and the presence of ozone is an unmistakeable sign that there is a complete absence of organic impurity. In great industrial centres where a pure air is needed most the murkiness of the atmosphere acts as an effectual barrier against the rays, and therefore their beneficent work is largely hindered. The plea for the ultraviolet rays is therefore merely the plea for sunshine itself. Later investigations have shown that the ultra-violet rays have an interesting action upon water, resolving part of it into hydrogen gas and peroxide of hydrogen. It has for long been maintained by some observers that the freshness of air, particularly after a welcome or long-delayed shower of rain, is due to peroxide of hydrogen, which readily oxidises organic matters or impurities with which it may come into contact. The presence of peroxide of hydrogen in the immediate proximity of waterfalls has also been suspected. Further, the ultra-violet rays are inimical to disease organisms. Whether this destructive action is due directly to the rays or to the oxidising products which they effect is a matter which has not received a definite answer. Amongst the best artificial sources of ultra-violet ravs is the quartz mercury lamp. This, when immersed in clear water infected with ordinary microbes and the coli bacillus, destroys those organisms within the radius of a foot in a minute. It is also a curious fact that the ultra-violet rays check fermentations. Lastly, it is probable that ultra-violet rays are largely concerned in the great assimilative processes

of plant life. It has been found, for example, that the assimilation of carbon by the leaves of wheat takes place about five times more rapidly when the sky is clear—that is, when ultra-violet rays obtain—than when it is cloudy. Altogether, the evidence of experiment is in favour of the conclusion that the ultra-violet rays fulfil a rôle of benefit to the human race, and the further study of their nature and action will be watched with interest.

WE are informed that Miss Pollok and Mrs. Gilchrist, the sisters and legatees of the late Dr. Robert Pollok of Glasgow, have given out of the estate which they inherited from him the munificent sums of £10,000 each to the Victoria Infirmary and the University of Glasgow for the endowment of a ward to be called the "Dr. Robert Pollok" ward and of a lecture-ship for original research in materia medica respectively. It is understood that these gifts are made in accordance with the written suggestion of the late Dr. Pollok, who throughout his career displayed a broad and unostentations charity. Scottish medicine owes a deep debt of gratitude to the ladies who have fulfilled the wishes of their dead brother in a manner worthy of his memory.

Dr. Anton Dohn, whose death has been announced recently, was well known amongst students of natural history as the founder, and for many years director, of the Zoological Station in Naples; he was born in 1840 in Stettin, his father being an eminent entomologist as well as a Member of Parliament. He studied zoology in Jena, and afterwards by means of a scholarship from the Berlin Academy of Sciences and with grants from various other scientific bodies he was able to found the station in Naples, which has been the means of enabling students of natural history from all countries to prosecute their studies under the most advantageous conditions.

A TELEGRAM from the Governor of Mauritius to the Secretary of State for the Colonies stated that 24 cases of plague with 13 deaths were reported during the week ending Oct. 7th.

THE DANGERS OF THE DRY SHAMPOO.

I.—THE RECENT FATALITY AT A HAIR-DRESSING ESTABLISHMENT FROM THE USE OF CARBON TETRACHLORIDE AS A SHAMPOO. THE INQUEST AND PROSECUTION FOR MANSLAUGHTER. II.—FURTHER EXPERIMENTS ON THE TOXICITY OF PURE AND COMMERCIAL TETRACHLORIDE, BY V. H. VELEY, D.Sc., F.R.S.

I.—The Inquest and Prosecution.

THE recent death which occurred during the application of a dry shampoo with carbon tetrachloride at Messrs. Harrods' Stores on July 12th has attracted considerable public attention and has been the subject of exhaustive inquiry. Briefly the circumstances of the case are as follows.

Miss Dalrymple, a young lady who, according to the evidence of all her intimate friends and relatives, had always enjoyed excellent health, went on July 12th to Harrods Stores for a dry shampoo. She was told by the assistant in the hair-dressing department that "it might make her feel ill," but she decided to undergo the process. The operation, according to the evidence, was conducted in the usual manner. After it had continued for about two minutes the lady turned pale and leant forwards over the basin and collapsed. Miss Dalrymple was placed by the assistant on the floor and help was called for, but she did not speak again and ceased breathing two or three minutes after. Artificial respiration and other measures were applied with no avail.

Mr. Luxmore Drew held an inquiry as to the cause of death at the Coroner's Court, Kensington, and during the course of this it was stated by the manager of the hair-dressing department of Harrods' Stores that carbon tetra-chloride had been used there for six years, that all

shampooing assistants were allowed to use it, and that cases of slight faintness had been seen.

Dr. W. Paul Jones stated that he was called in immediately to see the deceased lady. Death had occurred before his arrival. He found the odour of tetrachloride of carbon strong in the cubicle. He also stated that in February, 1907, he had been called to see a lady who had been faint during a shampoo and who had a rapid, irregular pulse on his arrival. The lady was healthy. Dr. Jones then suggested that fans should be used, and this suggestion was adopted. He had heard of several cases of slight faintness and had seen one case where the patient was quite insensible.

Dr. B. H. Spilsbury, pathologist at St. Mary's Hospital, made the post-mortem examination. He found signs of status lymphaticus in the deceased, and expressed the opinion that the cause of death was syncope due to status lymphaticus accelerated by carbon tetrachloride. He said that "if deceased had not inhaled tetrachloride she would not have died."

The verdict arrived at by the coroner's jury was "Accidental death accelerated by the fumes of tetrachloride of carbon," and they added a rider—"That Harrods' Stores were not justified in employing an unskilled operator to perform this dangerous operation."

On August 25th a prosecution was instituted by the Director of Public Prosecutions on the charge of manslaughter against the manager of the hairdressing department of Harrods' Stores and the assistant who gave the fatal shampoo. Mr. Leycester and Mr. Travers Humphreys appeared for the prosecution.

Mr. A. J. Pepper gave important evidence as to the dangerous nature of the process and the impossibility of safeguarding against possible dangerous effects of the vapour in spite of the precautions taken as regards ventilation during the process. Mr. Pepper described the process of the dry shampoo with tetrachloride of carbon which he, in conjunction with Mr. Chaldecott, had witnessed at Harrods' Stores. Both he and Mr. Chaldecott independently noticed unmistakeable symptoms showing that the lady on whom the operation was performed had inhaled some of the vapour. This was indicated by a distinct cyanotic tinge of the lipsand face. Mr. Pepper stated that there was a powerful odour of tetrachloride of carbon, especially in the lower part of the cubicle, and that "no one could possibly have breathed the air near the floor for more than a few seconds." pointed out that in the fatal case which had been the subject of inquiry the placing of Miss Dalrympleon the floor after fainting was the worst possible procedure. since here a larger dose of the vapour would be inhaled. Heexpressed the opinion that status lymphaticus could not alone account for death, and that the important factor in causing death was the inhalation of carbon tetrachloride.

Mr. J. H. Chaldecott, honorary anæsthetist at St. Mary's Hospital, gave evidence as to the use of carbon tetrachloride as an anæsthetic in former years, and pointed out that its use was abandoned for this purpose owing to the dangerous effect of the drug on the heart. He stated that it was a powerful anæsthetic, that a person having a dry shampoo with the substance was likely to inhale some of the vapour, and therefore the same precautions should be taken as when an anæsthetic was administered—viz., previous medical examination and loosening of the clothing to allow free breathing.

Dr. W. H. Willcox, senior scientific analyst to the Home Office, gave evidence as to the dangerous nature of the substance used for the fatal shampoo. He pointed out that while pure carbon tetrachloride was more poisonous than chloroform the commercial samples, such as the one actually used, contained over 2 per cent. of carbon di-sulphide, which impurity greatly added to the poisonous properties. He had conducted a large number of experiments on animals with the substance actually used in this fatal case, and all of these absolutely proved that the liquid was a very dangerous poison. He expressed the strong opinion that no precautions could make the use of it as a dry shampoo safe. He pointed out that the few cases of fainting stated to have occurred at Harrods' Stores could not be rightly taken as representing all the cases of illness from the substance, since frequently the symptoms are delayed for some hours, and some people who have had a dry shampoo would, no doubt, have suffered from vomiting and illness afterwards just as happens to people who work with the drug in laboratories. Dr. Willcox stated that he had performed experiments which proved that the substance used would rapidly evaporate, and to such an extent

that it was possible in a few deep breaths for a healthy person to take a fatal dose. He stated that he had had considerable experience of status lymphaticus, and that in this case the immediate cause of death was, in his opinion, undoubtedly due to the inhalation of carbon tetrachloride.

Lieutenant-Colonel E. Lawrie, I.M.S., stated that he had been medical attendant of the Dalrymple family and had known the deceased for a number of years. In his opinion she was quite healthy and the only cause of death was inhalation of carbon tetrachloride.

Dr. Spilsbury repeated the evidence he had given before the coroner's jury, and stated again that death must have been accelerated by the inhalation of tetrachloride of carbon.

Mr. Bodkin, for the defence, said that he had no complaint to make at the institution of the prosecution, and stated that Messrs. Harrods, on learning that carbon tetrachloride was dangerous to certain people, immediately gave orders that this preparation was never again to be used in their establishment.

Mr. Leycester, on hearing the steps taken by Messrs. Harrods, consented to the withdrawal of the charges of manslaughter. He pointed out that the prosecution had served the purpose for which it was intended in bringing to the notice of the public the dangerous nature of the dry shampoo where carbon tetrachloride was used, and also that it would be a severe warning against the use of this substance by any other persons for that purpose, since if any future deaths occurred a serious charge would of necessity be instituted.

The learned magistrate, Mr. Horace Smith, agreed with the course taken to withdraw the prosecution.

In view of the important evidence which has been published in connexion with the case, we feel sure that the Pharmaceutical Society will consider it desirable to make a recommendation to the Privy Council to place carbon tetrachloride on the Poisons Schedule. We consider that the public should in future fully realise the dangers of the dry shampoo, not only when carbon tetrachloride is used but also with many other preparations extensively employed. Carbon tetrachloride probably came into use because it was not inflammable, though, as is evidenced above, it has other very serious dangers. Many of the preparations which are used for the dry shampoo are dangerously inflammable, and numerous serious cases of burning have resulted, while a terrible tragedy of this sort has just occurred.

Our readers will remember that in THE LANCET of August 7th we published an important note by Dr. Augustus D. Waller on the relative toxicity of chloroform and carbon tetrachloride, with a note by Dr. V. H. Veley on the danger of the latter substance as a dry shampoo. We are now enabled to print an account of further investigations by Dr. Veley on its toxicity.

II .- Further Experiments on the Toxicity of Pure and Commercial Carbon Tetrachloride, by V. H. VELEY, D.Sc., F.R.S., Physiological Laboratory, University of London.

In consequence of the important case upon this matter recently before the court, I have, in the absence of Dr. Waller, carried on experiments, supplementary to those already described in THE LANCET, on the comparative effects on isolated muscle of (1) pure carbon tetrachloride as against pure chloroform, and (2) pure carbon tetrachloride as against the same substance to which carbon disulphide had been purposely added in the proportion of 2 per cent.—namely, that in the commercial article. The sample of pure carbon tetrachloride was obtained by the fractional distillation of the commercial article; its physical properties, boiling point, density, &c., were in accordance with those found by Thorpe, Young, and previously by myself.

The experiments were conducted in the usual manner namely, to obtain the normal response from muscle in saline solution, then to substitute the chemical compound and continue until abolition of response took place, then again to put back into saline solution in order to ascertain the recovery, if any

1. Pure oarbon tetrachleride as against pure chloroform .-Solutions of both these substances were made up to $\frac{-}{100}$ contained 0.1538 per cent. carbon tetrachloride, and 0.1194 per cent. chloroform respectively, neglecting variations of density of water; the substances were weighed out to within 1 part in 500; the former solution was subsequently diluted as required.

First series of experiments. Substances both of $\frac{n}{100}$ concentration. Times required for abolition: chloroform 14', carbon tetrachloride 17'; good recovery in the case of the former, no recovery in the case of the latter.

Second series of experiments. Carbon tetrachloride $\frac{n}{150}$ chloroform $\frac{n}{100}$. Times required for abolition : chloroform 13', carbon tetrachloride 28'; recoveries as before.

Third series of experiments. Carbon tetrachloride $\frac{n}{130}$ chloroform $\frac{n}{100}$, being approximately the proportion of equal weights. Times required for abolition: chloroform 13', carbon tetrachloride 24 5'; recoveries as before.

Hence, therefore, though the action of carbon tetrachloride is less rapid than that of chloroform, its action is more deadly, as the muscles recovered from the toxic effects of the chloroform, but were killed by the carbon tetrachloride.

2. Pure carbon tetrachloride as against the same with 2 per cent. carbon bisuiphide. - The former solution was the same as that used in the experiments described above; the latter solution contained 0.1538 per cent. tetrachloride and 0.003 per cent. carbon disulphide. It might be an open question whether the latter substance really dissolved or only formed an emulsion with the water, but, however this may be, the liquid thus obtained had an odour quite identical with that of a similar liquid obtained from the "dry shampoo." Two series of experiments gave the following results:

Times required for abolition.

			re car		th 2 per c 1 disulphi	
First series					16'	uc.
Second series	•••	•••	20'	 •••••	14'	
Mean value			20′	 	15'	

There was no recovery in any case.

Hence, therefore, since the toxic or lethal values are inversely proportional to the times, one has the ratio 15:20::100=133, or, to put the matter in other words, the 2 per cent. carbon bisulphide purposely added increases the lethal value by as much as 33 per cent. It may further be mentioned that a solution (or emulsion) containing 0.1 per cent. carbon disulphide, obtained from a sample of hair-wash, killed an isolated muscle immediately.

It is to be hoped that the public warning may suffice to stop the use of carbon tetrachloride by unskilled and untrained persons.

MOTORING NOTES.

The Red Cross Doctors' Policy.

THE Medical Insurance Committee (see p. 1160) has had under consideration for some time the question of motor-car insurance, and is now in a position to recommend insurance at Lloyd's under a policy which is better calculated to meet the practical needs of motor-car owners than any other which has been inspected. It is well known that the sale value of a car purchased new deteriorates very rapidly. medical man may, for instance, purchase a new car for £700 and insure it for that amount, paying a premium on that sum annually; if, however, his car becomes a total loss three or four years later he would under ordinary circumstances receive not the replacement value, £700, but the sum at which the car is valued at the time it came to grief. A car bought new for £700 would probably in its third year not be valued at one-half that amount, although its usefulness to the owner would not have greatly diminished. The policy which the Medical Insurance Committee recommends meets this objection, since the insured value is agreed as the replacement value. Thus, in the event of total destruction or loss, the full amount insured is paid concentration in physiological saline solution, and therefore of the car and accessories and by its horse-power; for instance, on a 10 horse-power car and accessories valued at £300 the annual premium is £11 10s, and for a 14 horse-power valued at £400 the premium is £14, and so on. The rates quoted are those of the "Red-Cross" doctors policy, and the premiums cover (1) all damage to car the direct result of accidental collision, excluding wilful damage, wear and tear, and mechanical breakdown; (2) all claims for which the assured may be liable for injury to persons (excluding passengers) and animals, or damage to vehicles or property while being towed or conveyed by road, rail, or inland waterway, anywhere in the United Kingdom; (6) damage to lamps and accessories due to accidental collision, and damage to tyres from the same cause when the car also is damaged. Further, compensation of £1 a day is paid during the time the car is being repaired owing to an accident, to cover the cost of hiring a conveyance; this compensation is payable from the second day after the receipt from the repairers of the assured of an estimate for the repairs until the repairs are actually completed, but the allowance for hire of a conveyance will not be paid beyond 75 per cent. of the agreed cost of repairs. There is no restriction as to driver, all damage to the car being covered while any licensed person is driving, whether with or without the knowledge of the assured. If no claim is made in a year an amount equal to 25 per cent. of the full premium paid will be returned in cash. If the owner only drives there is a reduction of 5 per cent., and if the same owner owns two cars, only one of which is used at a time, there is a reduction of 20 per cent. on the combined premiums; if both cars are liable to be in use at one time the reduction is 10 per cent. The owner's liability with regard to his paid driver, accidents to the owner or passengers in the car, and theft of accessories can also be provided against under these policies for small additional premiums.

The Medical Insurance Committee is able to allow 10 per cent. off the total premium paid by the insurer. Special policies are also issued to owners of certain makes of cars, authorising them to have repairs up to any amount commenced immediately without consent at the authorised agents of the particular company, but for a medical man the "doctors' policy" would seem to be the best. Red Cross policies are also issued without the provision above mentioned for compensation while the car is being repaired, and can be made to cover mechanical breakdowns under certain conditions, the premiums being adjusted accordingly. A full prospectus of these may be had on application to the secretary and agent at 429, Strand, London, W.C.

The Olympia Motor Exhibition.

The only International Exhibition of Motor-cars this year will be held at Olympia, London, from Nov. 12th to 20th. This will be the eighth held by the Society of Motor Manufacturers and Traders, and as there will be no exhibition in Paris this season a large influx of visitors and buyers is expected. About 300 firms will be displaying their wares and a moderate estimate of the motor-cars on exhibition would be 600, whilst in addition there will be all kinds of engines, types of electric ignition, lamps, clothing, and tyres. Special trains at cheap fares will be run by the railway companies from the chief towns in the provinces, and doubtless many medical men, hesitating or on the verge of changing from horse-driven to petrol-propelled vehicles, will take advantage of these special railway facilities to visit the show, where the latest ideas in motor construction will be on As last year, the number of THE LANCET which is published on the same day as the exhibition opens will contain a description of the show, and especially of such exhibits as are likely to be of interest to the medical motorist.

THE autumn dinner of the Glasgow University Club, London, will be held at the Gaiety Restaurant, Strand, on Friday, Nov. 5th, at 7.30 P.M., when Lord Rosebery, Chancellor of the University, will preside. Members who intend to be present, or to introduce guests, are requested to send notice at once to the honorary secretaries, 4, Bryanston-street, Portman square, W.

THE JUBILEE OF THE CRANLEIGH COTTAGE HOSPITAL.

JUST half a century ago there was opened in the Surrey village of Cranleigh (or Cranley, as it was then spelt) the first cottage hospital in England, and this, the month of its jubilee, is a fitting occasion to recall the inception of a class of institution which has become familiar in every part of the country, and which in spite of certain adverse criticisms has largely justified the intentions of its founders. To those who are accustomed to the neat brick-built bungalow buildings, which in their equipment and design are microcosms of the larger county institutions for the sick poor and with which the name of cottage hospital is in most instances associated at the present day, it may come as a surprise to learn that the word "cottage" was accurately descriptive of the prototype of them all. The medical founder of Cranleigh Cottage Hospital was the late Mr. Albert Napper. Mr. Napper, who at one time was associated with this journal, has been dead 15 years, but he is still remembered by many of his friends, for he gained the respect of his neighbourhood as a skilful surgeon, a keen sportsman, and a humane and open-hearted country gentleman. The idea of the cottage hospital was driven home to Mr. Napper by the frequent occurrence in his practice of cases of serious illness that could not be given the treatment necessary for the patients and satisfactory to himself in the poor and frequently unhealthy surroundings of an agricultural labourer's dwelling, whilst he had frequently found it difficult or impossible to induce such patients to leave those homes to enter the county hospital at Guildford some miles away. They dreaded the unknown environment of a large institution and wished to remain in the hands of the man they knew and trusted. Others who had met with accidents might have been induced to enter a large hospital but would have undergone serious risk in the journey over country roads necessary to reach it. These facts had also struck the late Archdeacon J. H. Sapte, rector of the parish, who having a convenient old cottage in the village, offered it rent free to be equipped as a hospital for the use of a limited number of poor people needing careful attention whilst undergoing medical or surgical treatment. The scheme aroused interest in the neighbourhood and a small committee was formed to put it into execution, with the result that the following rules, amongst others, were framed for the conduct of the little hospital:

The hospital is designed for the accommodation of the poor when suffering from sickness or accident.

The establishment shall consist of a regular nurse, and another woman for the regular work of the house.

The nurse shall, at such times as her services are not required in the hospital, attend poor women in their own homes during their confinements or other illnesses, on the payment of the usual fee.

Patients shall be received on the payment of a weekly sum, the amount of which, dependent on their circumstances, is to be fixed by their employer, in conjunction with the manager of the hospital, who shall grant admission on consultation with the medical officer.

The funds for the establishment and support of the hospital shall be raised by voluntary contributions.

It was further provided that Mr. Napper should be the medical officer, but that cases admitted from the practice of neighbouring medical men should be visited by them so that they might have a voice in the treatment. A lady volunteered to give her help to the establishment in special cases. excellent rule (which has been followed since the foundation) was that parish patients might be received into the hospital for operative or other treatment, in which case the Poor-law medical officer who attended them was entitled to recover from his guardians the special fees sanctioned by the Local Government Board. The idea of the founders was to reproduce, as far as possible, the kind of life to which their patients were accustomed in their own homes, only replacing cleanliness and decently served and cooked meals for the dirt and illfeeding which were then, as now, only too common in many rural homes.

The building which was adapted to this purpose by the rector's generosity was an old and picturesque two-storey cottage. It is well shown in our illustration, and did duty until 1901, when the single-storey brick hospital, part of which can be seen behind the old cottage, was erected to meet the demands of modern surgery, the cottage being converted to the use of the nurse and the kitchen department. As it was originally used, the two chief bedrooms on the upper floor were made into wards for three male and three female patients respectively, a smaller room was employed for operations, another tiny apartment for the nurse's bedroom, and the large room downstairs was the kitchen and sitting-room for convalescents, the furniture being that of a decent cottage kitchen-parlour. Very pleasant the old place is to-day, with its wealth of black oak beams and spotless white walls, although the patients have left it for the two modern wards, properly equipped for aseptic treatment, separated from their excellent bathrooms and lavatories by properly crossventilated passages. These wards will accommodate two more patients than was formerly possible in the old building. The bathroom is not an innovation, for considerable trouble was spent in erecting a bath with hot and cold service in the original hospital, which thus boasted a possession perhaps unique amongst the English cottages of the middle of last century.

The late Mr. Albert Napper, M.R.C.S. Eng., L.S.A., medical founder of the first Cottage Hospital.

The new hospital has an operating room which in lighting and arrangement is all that can be desired, a feature that, as many of our readers know, is now common to these institutions.

The history of the Cranleigh Hospital has been almost uneventful in its prosperity, the chief incidents present having been the retirement of its medical founder in 1881 (when he was presented with a testimonial which was largely subscribed by the medical profession and which THE LANCET did its best to promote), and the move into the new quarters eight years ago. The managers have wisely contented themselves with improvement rather than expansion-the present hospital contains only two beds more than the old buildingwith the consequence that it has never had to face an adverse balance-sheet. In the four years after its opening it received 100 villagers at a total cost of £612, of which £131 were contributed by the patients themselves; and we find by the last annual report that 65 cases were treated during the year, with an average stay of 2 33 days each. Several serious

Cranleigh Cottage Hospital. In the front is the old building, shaded by the tree. At the back is one of the main wards of the present hospital.

surgical emergencies and a good number of accidents were treated, but cases of chronic illness are not received unless they require relief for urgent symptoms; and it is not usual to receive domestic servants, the institution having been specially intended for poor country folk. It is satisfactory to note that the receipts from patients amounted last year to £48 10s., a good sum in relation to the number treated, especially when we remember that it is drawn from a poor class in return for attendance, which would probably have left any medical man out of pocket who treated the patients for the customary fees in their own homes. It is clear that no case can be made out in this instance for the existence of "hospital abuse," and this is endorsed by the practical interest which Cranleigh and the neighbourhood take in supporting its little hospital.

The management has continued on its original lines with a few modifications. Mr. Arthur Napper, the present medical officer, succeeded his father in that post, in which Dr. A. H. Walker and Dr. J. K. Willis are now associated with him. The policy of inviting neighbouring practitioners to attend their own cases in the hospital has been maintained, and in this manner an ethical difficulty, which has been unfortunately prominent in connexion with several larger hospitals, has been averted. Quite recently a new post has been made, that of consulting surgeon, to which Mr. Stansfield Collier has been appointed, and we are convinced that cottage hospital managers throughout the country would do well to create similar posts where they do not already exist. The surgical skill of the country practitioners who attend the poor in cottage hospitals is not called in question by the proceeding; it is simply a recognition that many operations are now performed which were undreamt of in the middle of last century. Cases must sometimes arise in which the patient will have an appreciably better chance of recovery if operated upon by a man who devotes his whole time to the practice of surgery, and who perhaps has performed the operation in question a very considerable number of times more than opportunity has made possible for the local surgeon. In the vicinity of most cottage hospitals there are towns in which men practising pure surgery live, and from these towns cottage hospitals could easily draw consultants and thus reinforce their useful and truly charitable system for the relief of the sick poor.

The interest aroused by the opening of the Cranleigh The interest aroused by the opening of the Cranleigh Cottage Hospital at its inception was not confined to Surrey. In the early "sixties" a great many general newspapers, besides all the leading medical journals, described the experiment, and for the most part spoke of it in enthusiastic terms. THE LANCET called it "a sensible and useful development of local philanthropy, for which we desire permanence and a rich fruition of useful work," and we are cled to take the present expectation to record the fulfilment. glad to take the present opportunity to record the fulfilment of our predecessors' good wishes. The *Times*, the *Saturday Review*, *John Bull* (the first of that ilk), the *London Review*, the Scotsman, and a large number of provincial journals gave full descriptions of the hospital and its methods, and from a lengthy contemporary article in Good Words we learn that Fowey and Bourton-on-the-Water were not long in adopting the Cranleigh lead. East Grinstead and Tewkesbury were also early in the same field and within ten years there were nearly a hundred cottage hospitals built or building in various parts of the country, most of them having adopted the Cranleigh constitution for a model. In 1881 we recorded the existence of over 300 similar hospitals in the United Kingdom as well as of many in the colonies, on the continent, and in America. Their popularity has never waned, and at the present day it is probable that most of our readers in the country are in active touch with one of them, and we believe that their work will stand the criticism of results. Of their popularity with stand the criticism of results. Of their popularity with their poor beneficiaries there can be no question, and we see no reason why, if worked on the system which we have described, they should excite the opposition of any branch of the medical profession, seeing what good fruit has already sprung from the stock first planted and tended with devotion by that worthy surgeon Albert Napper.

DONATIONS AND BEQUESTS.—Under the will of the late Rev. E. L. Adams, the Manchester Royal Infirmary will receive £4000, upon the condition that a ward in the institution be named the "Elizabeth Adams Ward."

PERIODICITY IN EPIDEMIC DISEASE IN MELBOURNE.

AUTHENTIC information respecting sanitary matters in Australasia is highly appreciated in the mother country, and the interchange of ideas made practicable by the discussion of such information proves advantageous to the dwellers in all parts of the Empire. The latest mail brings us from Melbourne an instructive essay on the periodicity of epidemic diseases in that city, reprinted in pamphlet form from the transactions of the Australasian Medical Congress. The author is Dr. James Jamieson, the medical officer of health of Melbourne, who has utilised the occasion of the meeting recently held in that city to introduce this topic for discussion by his professional colleagues.

British epidemiologists will be particularly interested in this essay, for it shows that if due allowance be made for the wide differences, geographical and other, between Australia and this country, the incidence of epidemic mortality in both regions of the globe is, in many respects, similar. Dr. Jamieson selects for particular comment enteric fever, scarlet fever, diphtheria, and influenza the first three of these being those with which his duties as guardian of the public health bring him into most intimate contact. Except incidentally Dr. Jamieson does not attempt to compare the seasonal distribution of epidemic disease in his own city with that which obtains in this country. We surmise that this is because the information at his disposal is limited to fatal cases of disease, whilst concerning the far greater amount of sickness which, happily, is "not unto death" the Melbourne authorities possess no record. For the information of our Australian brethren we may mention that under a general Notification Act every sanitary authority in England is compulsorily furnished with the name and address of every person suffering from any of the more dangerous epidemic diseases, and consequently a vast amount of material is accumulating here which, if properly analysed and registered, should eventually furnish accurate information respecting the very points discussed in the present essay; and this information would be available for comparison with similar data for the colonies as soon as they are ready to utilise it. That the health officer of Melbourne desires similar equipment for his own city we gather from the following passage in his essay: "A special point in the history of the epidemic diseases (in Melbourne) is the liability which they show to successive periods of increase and decline, in prevalence, and in fatality. The problem in connexion with this would be simplified if there were a constant ratio between these, since, even in the absence of any exact returns as to prevalence, it would be sufficient to know the number of deaths in a given period. This is not the case, however, since almost all epidemics have a varying degree of virulence and of mortality at different periods. Scarlet fever has this peculiarity perhaps more than any other disease. In the early years of its appearance in Victoria it was looked upon as a trivial ailment, whilst the great outbreak of 1875-76 showed a severity which must be described as excessive. Again, in recent years the mortality has been actually trifling. Of these alternations we have as yet no approach to an explanation, and can only postulate some cosmic conditions as operative in their production." This being so, the omission to which we now call attention is a little puzzling. Dr. Jamieson illustrates his essay by means of a series of charts which, with the belp of his assistant, Dr. Walter E. Summons, have been carefully drawn to scale and which add materially to the value of the work. Much labour has evidently been expended on these charts, which relate to the mortality from epidemic diseases for a series of years, but the chief meteorological data, such as temperature, rainfall, and atmospheric pressure, which in this country are usually appended to diagrams of this kind, have been omitted.

Dealing with the question of epidemic prevalence generally, the writer remarks that at longer or shorter intervals there occur in Australia severe outbreaks, followed by periods of diminished prevalence or complete cessation. In isolated districts this may be merely a question of fresh introduction of infection from without. But in districts where the disease is always more or less present recurring outbreaks

are probably due to the growing up of a fresh body of susceptible subjects. While in either of these ways it may be possible to account for the recurrence of outbreaks at intervals more or less regular, they supply no explanation of the fact that the same disease shows a varying degree of virulence and of fatality at different times. reference to the incidence of scarlet fever mortality Dr. Jamieson's experience confirms that of this country, that the disease shows a marked tendency to increased prevalence in autumn, with a climax of severity in September. This is the case in Melbourne, for a similar tendency is seen there at the corresponding season—that is, in March. The character of the curve is convincing as to the general tendency to increased prevalence from October to March, with a corresponding decline to October again. It might be supposed, he suggests, that the rise to a maximum in March is related to school attendance. But in a rather slowly spreading epidemic like scarlet fever there would appear to be nothing in such an explanation adequate to account for the rapid fall in April. To assume a varying susceptibility in the child-population at different seasons, or some corresponding variation in activity of the infecting agent, is mere theorising. Moreover, it has to be noted, as against such a hypothesis, that the climax in diphtheria falls in May, though the two diseases have the same proneness to localise their early manifestations in the fauces.

By means of a chart relating to diphtheria in Melbourne it is shown that, as in Europe and in America, this disease is far more fatal there in the colder months of the year and less so in the warmer. How regular is this seasonal recurrence when account is taken of a large number of cases spread over many years is shown by the curve, which, in the uniformity of its ascent and descent, is remarkable. Discussing the probable causes of the increased prevalence of diphtheria at this season of the year Dr. Jamieson passes in review some suggestions emanating from this country and elsewhere. Among these is one that the winter prevalence of this disease depends largely on the concurrent presence of catarrhal affections of the nose and throat, but it is dismissed by the author with the remark that whereas catarrhs are never so common as they are during influenza epidemics, no concurrence is observable when the curves of these two diseases are exhibited in the same diagram.

Among the commoner diseases of the epidemic class enteric fever is the one that most perfectly illustrates what may be termed cyclical periodicity—i.e., the recurrence at regular intervals of outbursts of illness of great extent or severity. This disease, as it occurs in Australia, is dependent more than any other on external conditions; in only slight measure is it directly contagious; it has no special liability to affect children; and it has a regular seasonal periodicity. Up to 1890 the disease seemed to run riot in Melbourne, whilst from 1891 to 1907, during which period there have been improvements in sanitation and steady extension of sewerage works, typhoid pre-valence has been reduced to quite a low level. In the first of these periods there are clear signs of a tendency to severe recurrence at intervals of four years, whilst in the second the mortality varies little from year to year. In the first the inhabitants of the city were left almost at the mercy of external influences, whilst in the second such conditions were either curbed or kept in abeyance. "It is fortunate," adds Dr. Jamieson, "that though we have no solution of the theoretical problem we have at least succeeded in attaining the valuable practical result of getting typhoid mortality reduced till it is in a fair way of becoming a vanishing quantity."

ASYLUM REPORTS.

Royal Albert Asylum.—The annual meeting of the Royal Albert Asylum (Training Institution for the Feeble-Minded of the Northern Counties), Lancaster, was held on Sept. 30th, at Bradford town hall, Lord Richard Cavendish, deputy chairman of the central committee, being in the chair. The report spoke of the loss by death of Sir J. T. Hibbert, the Marquis of Ripon, Earl Egerton, Sir Edward Lawrence, and other supporters, but said they had been fortunate in obtaining the services of the Earl of Lathom as chairman, and of Lord Richard Cavendish as deputy chairman and chairman of the house committee. The appointment of Mr. of this amount under all meteorological conditions, and some

E. Tootal Broadhurst was referred to as being very gratifying as chairman of the Manchester and Salford committee. subscribers were asked to give their approval to the incorporation of the asylum under the amended title of "the Royal Albert Institution, Lancaster." Incorporation would confer many advantages, and care had been taken to comply with the views of the founders, while the alteration of title would remove some of the disadvantageous associations connected with the word asylum. The fortyfifth annual report was testimony to the increased and increasing work of the institution. There are now 678 inmates, 431 males and 247 females. 292 were election cases, an increase of 22 during the last two years, and 332 were cases received at reduced rates of payment. There were 273 patients from Lancashire, 210 from Yorkshire, 63 from Cheshire, 59 from Durham, 31 from Cumberland, 20 from Northumberland, 16 from Westmorland, and six from other The average number resident during the year had been 661, as against 647 in the previous year. With increasing numbers increased support is necessary, which the committee confidently look for, although from the severe depression of trade there was some decrease in the year's subscriptions. The inmates of the institution were said to look cheerful and happy, as well as being neatly dressed. During the year there had been 65 admissions, 34 discharges, and 13 deaths. The aggregate number under treatment during the year had been 725, 682 being the highest number resident on any one day. Of the 34 discharged, there had been material improvement in 13 cases, moderate improvement in ten, and nine others showed slight improvement. The deaths showed a percentage of only 1.79 of the aggregate number under care. There has been a considerable strain on the resources of the infirmary as to space, and Mr. Archibald R. Douglas therefore recommended the erection of an inexpensive building for the quarantining of infectious cases. The value of such an institution as this is far greater than is indicated by the mere numbers given. It is to be hoped that in time the whole nation will be alive to the necessity of maintaining life-long control of these unfortunate members of the community, and not be satisfied that in early adolescence the feeble-minded ones shall beunprotected and left to their own devices.

THE CHEMICAL PRESERVATION OF JUG-CREAM.

Under the exigencies of our present-day existence and by virtue largely of our insular position traders are compelled in the case of many of our foods and drinks to resort to some method of preservation. By the introduction of substances which are also prescribed for use as drugs fraught with physiological results they have been able to introduce and retain in grocers' and fishmongers' shops foods which without such medicines might have betrayed their presence in unpleasant fashion. On the other hand, the employment of these chemical preservatives, such, for example, as salicylic and boric acids, has in the past placed a discount upon cleanliness and freshness by enabling less care to be exercised in the choice and preparation of the original articles. It is said, for instance, that the unwholesome conditions under which certain firkin butters are prepared would long have ceased were it not for the large amount of preservatives which are added to them. But it is alleged that in the case of certain foods it would not be practicable to rely entirely upon methods of preservation such as cleanliness and the application of cold or heat, since sometimes these methods render the foods unpalatable, and therefore unsaleable. In the case of milk the Departmental Committee on Preservatives and Colouring Matters in Food recommended in 1901 that in no circumstances should any chemical preservatives be added, since it was able to show that under existing arrangements an invalid infant might easily, day by day, have unconsciously administered to it far larger doses of certain drugs than would be prescribed for an adult by the physician. But as regards cream, it was decided that provisionally boric acid or mixtures of boric acid and borax might, if declared, be added in amounts not exceeding 0.25 per cent. expressed as boric acid (H₃BO₃). At that time there were but few experimental data available as to the effect

of the small dealers in jug-cream have, it appears, experienced difficulty in carrying on their trade during the hotter months with this maximum. Accordingly Dr. J. M Hamill, one of the food inspectors of the Local Government Board, has recently investigated the subject from the point of view largely of the jug-cream traders. The result of his investigation is to show that a cream trade can be carried on without the use of any preservatives at all by large firms who send their cream direct to their customers; but that there are great difficulties in the case of the "indirect" cream trade, where it is desired to keep the cream fresh for a week in retailers' shops. It is, in fact, alleged that without preservatives the jug-cream trade could not exist at all, especially in summer a consummation which has apparently been reached in Germany and America, where no preservatives whatever are allowed in cream. France, however, where presumably no preservatives are actually allowed, appears to be doing a thriving trade, both in her own and in this country, in jugcream, but whether or not her home trade is conducted by some other method of preservation it seems clear that the cream which reaches this country from France contains a considerable amount of chemical preservatives.

In so far as the United Kingdom is concerned, it certainly seems, on a basis of careful experimentation by Dr. A. Harden at the Lister Institute, that in the summer months an addition of 0.15 per cent. of boric acid to the maximum provisionally laid down by the Preservatives Committee may be necessary from May to October inclusive, the maximum of 0.25 per cent. remaining operative during the rest of the year, and this forms one of Dr. Hamill's recommendations. It has, however, been necessary to provide against the addition of this amount of preservative to very thin cream-such, for example, as that which contains as little as 8 to 9 per cent. of fat, and which might be consumed, with its attendant 0.4 per cent. of boric acid, in large quantities with undesirable results. It has, therefore, been recommended that the cream to which the limits of boric acid above referred to are added should contain at least 40 per cent. of milk fat. In all cases the declaration of the preservative should, Dr. Hamill thinks, be made compulsory and adequate and not, as at present, in microscopic letters in out-of-the-way corners of the labels. Some dealers have, it seems, recently intimated on the label that boracised cream is not suitable for infants and invalids, and there is obvious advantage in a declaration such as this; in fact, if it is made and if the amounts of boric acid prescribed are never exceeded the risks should prove practically negligible.

But, nevertheless, there is much to be said for the way in which they deal with these things in the Fatherland-i.e., entire prohibition of all chemical preservatives in cream. Dr. Hamill points out in his report that, notwithstanding the recommendation of the Departmental Committee above referred to, boric acid in definite proportions should be the only preservative permitted in cream. There is a general disposition on all sides to accept this recommendation and to act upon it in the law courts, but nevertheless efforts are being made to introduce in addition into the cream other preservatives, such as sodium salicylate or sodium benzoate, these preservatives being used to reinforce the preservative effect of boric acid. The fact that these additional preservatives are an infringement of the recommendations of the Departmental Committee is quite well known to those who employ them, and who apparently act in the belief and hope that if the analyst finds boric acid in amounts not in excess of the maximum he will not pursue his researches further, and, as Dr. Hamill crisply puts it, "there is reason to believe that their expectations in this respect are frequently realised." It also appears that sodium fluoride a sufficiently dangerous substance—is sometimes employed as a cream preservative.

Thus we are not altogether out of the wood in this matter of chemically preserved cream, and although there is no need for serious alarm, those who know the difficulty of searching for every conceivable preservative in every sample of cream may wish to have their cream labelled "guaranteed to be free from all preservatives" or to confine their consumption of cream to their visits to Germany. But perhaps if the traders obtain their additional 0.15 per cent. of boric acid during the summer months as a provisional concession pending further research and, it has to be added, also the

the Teutonic example be ultimately copied. The cream traders have been treated with great consideration and in a wholesome spirit of compromise by the food department of the Local Government Board, but they must remember that there is a limit to the chemical experimentation which should be carried on within the human test-tube.

MEDICINE AND THE LAW.

A Prosecution under the Public Health Act at Willesden. AT the Willesden second court recently Mrs. Rose Hibbard, residing at Harlesden, was convicted under section 126 of the Public Health Act, 1875, of wilfully exposing her son while suffering from scarlet fever, the evidence showing that the offence was not only of a dangerous character but was also followed by serious results for others. The boy was excluded from the school which he attended on Sept. 6th on the suspicion that he was suffering from chickenpox, and a health visitor on the following day warned the mother and instructed her to look out for signs of peeling. On Sept. 13th another health visitor called and found that desquamation was taking place, and on the 16th the medical officer at the school examined the child and diagnosed scarlet fever, again warning the mother. On the same day the boy was seen playing with others in the road where he lived, and he also took a ride in a baker's cart. Subsequently to this the mother called in the medical practitioner attending her family, who came to the same conclusion as the school medical officer, informed her, and notified the medical officer of health. There was evidence that the child attended the "Socialist Sunday School" after the mother had been warned, although the father, who was the secretary of the school, did not accept his wife's admission that this had been the case. Apparently as the consequence of the recklessness of Mrs. Hibbard two children of neighbours contracted the disease and became seriously ill, the medical evidence being to the effect that either of these resulting cases might have had a fatal termination. In the circumstances the Bench certainly did not err on the side of severity in inflicting a fine of 20s. and in declining to include the fees of the medical witnesses in the costs which the defendant was ordered to pay. This inflicts a hardship not upon the medical profession but upon the sanitary authority and upon the ratepayers. The public might justly have been relieved of as large a proportion as possible of the heavy expense incurred by it owing to the conduct of a person who, as the chairman of the Bench pointed out to her, was not able to plead ignorance or lack of power to understand the nature of her acts. The same gentleman observed that her own motherhood and natural sympathy with other mothers should have caused her to behave differently. It is to be hoped, however, that if the fine inflicted was light the weight of public opinion may make itself felt, and that both Mrs. Hibbard and her husband may realise that the community expects from its members consideration for others in such matters, although this may entail some slight trouble and self-sacrifice on the part of those exercising it. Even in a socialist state the equal distribution of disease by unrestricted infection could hardly be considered desirable, and the defendant and her husband can scarcely be regarded as practical exponents of such doctrines of unselfishness as may be included in the tenets of

VITAL STATISTICS.

socialism.

HEALTH OF ENGLISH TOWNS.

In 76 of the largest English towns 7920 births and 4066 deaths were registered during the week ending Oct. 9th. The annual rate of mortality in these towns, which had been equal to 13.0, 12.6, and 12.3 per 1000 in the three preceding weeks, rose again to 12.9 in the week under notice. During the 13 weeks of last quarter the annual death-rate in these towns averaged only 11 9 per 1000, and in London during the same period the rate did not exceed 11.4 per 1000. The lowest annual rates of mortality recorded in the 76 towns last week were 5.9 in East Ham, 6.4 in Rotherham, 6.5 in Croydon, and 7.1 in Hornsey; use of hydrogen peroxide as a preservative, they may think it the rates in the other towns ranged upwards, how-the better course to abstain from further sophistication lest ever, to 19.3 in Huddersfield and in Merthyr Tydfil,

19.5 in Bootle, and 21.1 in Bury. In London the recorded death-rate last week did not exceed 12.2 per 1000. The 4066 deaths in the 76 towns last week showed an increase of 187 upon the number returned in the previous week, and included 402 which were referred to the principal epidemic diseases, against numbers declining steadily from 849 to 431 in the six preceding weeks; of these 402 deaths, 230 resulted from diarrhea, 49 from whooping-cough, 40 from scarlet fever, 30 from measles, 28 from diphtheria, 24 from "fever" (principally enteric), and one from small-pox. The 402 deaths from these epidemic diseases last week were equal to an annual rate of 1.3 per 1000, a lower rate than in any week since the middle of August. No death from any of these epidemic diseases was registered last week in Plymouth, Birkenhead, South Shields, Rochdale, or in six other smaller towns; the annual death-rates therefrom ranged upwards, however, to 3.3 in Coventry and in Merthyr Tydfil, 3.4 in Salford, and 3.8 in Hanley. The deaths attributed to diarrhosa in the 76 towns, which had declined in the six preceding weeks from 676 to 263, further fell last week to 230, but caused annual death-rates ranging upwards in the several towns to 2:1 in Walsall, 2:4 in Gateshead, 2:5 in Hull, and 2:9 in Great Yarmouth. The fatal cases of whooping-cough, which had ranged in the six preceding weeks from 73 to 51, declined last week to 49, of which 21 occurred in London and four in Liverpool. The 40 deaths from scarlet fever showed a further increase upon recent weekly numbers, and included 12 in London and its suburban districts, seven in Birmingham and Smethwick, seven in Manchester and Salford, and two both in Liverpool and in Bolton. The 30 fatal cases of measles showed an increase of 13 upon the low number in the previous week, but caused annual rates equal to 1.3 per 1000 in Coventry and in Merthyr Tydfil, and 2.0 in Newport (Mon.) The deaths from diphtheria, which had been 37 and 43 in the two previous weeks, declined last week to 28, of which six occurred in London and its suburban districts, four in Manchester and Salford, and two in Hanley, in which town nine fatal cases of this disease occurred during last quarter. The 24 deaths referred to "fever" showed a further increase upon the low numbers in the two previous weeks, and included two in West Bromwich. The fatal case of small-pox, the first recorded in the 76 towns since the middle of May, occurred in the Metropolitan Asylums Hospital at Joyce Green. The number of scarlet fever patients under treatment in the Metropolitan Asylums and the London Fever Hospitals, which had steadily increased in the six preceding weeks from 2347 to 2737, had further risen on Saturday last to 2745; 324 new cases of this disease were admitted to these hospitals during last week, against 438 and 373 in the two preceding weeks. Of the 1127 deaths registered in London last week, 186 were referred to pneumonia and other diseases of the respiratory system, against 149 and 132 in the two preceding weeks, and exceeded by 19 the corrected average number in the corresponding week of the five years 1904-08. The causes of 32, or 0.8 per cent., of the deaths registered in the 76 towns last week were not certified either by a registered medical practitioner or by a coroner. All the causes of death registered during last week were duly certified in London, Leeds, Bristol, West Ham, Bradford, Newcastle-on-Tyne, Nottingham, Leicester, Salford, and in 49 other smaller towns; the 32 uncertified causes of death in the 76 towns last week included six in Liverpool, five in Manchester, four in Gateshead, and two both in Sunderland and in West Bromwich.

HEALTH OF SCOTCH TOWNS.

In eight of the principal Scotch towns 902 births and 428 deaths were registered during the week ending Oct. 9th. The annual rate of mortality in these towns, which had been equal to 13 · 8 and 13 · 1 per 1000 in the two preceding weeks, further declined to 12 · 0 in the week under notice. During the 13 weeks of last quarter the annual death-rate in these Scotch towns averaged 12 · 6 per 1000, and exceeded by 0 · 7 the mean rate during the same period in the 76 large English towns. The annual death-rates last week in these Scotch towns ranged from 7 · 2 and 10 · 2 in Greenock and Paisley to 12 · 7 in Glasgow and 14 · 8 in Dundee. The 428 deaths from all causes in the eight towns last week showed a further decline of 42 from the numbers in the

two previous weeks, and included 45 which were referred to the principal epidemic diseases, against 52 and 48 in the two preceding weeks. These 45 deaths were equal to an annual rate of 1.3 per 1000, and corresponded with the mean rate from the same diseases last week in the 76 English towns. The 45 deaths from these diseases in the Scotch towns last week included 18 from diarrhœa, 12 from diphtheria, seven from scarlet fever, four from "fever," three from measles, and one from whooping-cough, but not one from small-pox. deaths attributed to diarrheea in the eight towns, which had been 20 and 22 in the two previous weeks, declined to 18 last week, of which eight occurred in Glasgow, three in Dundee, and two each in Edinburgh, Paisley, and Leith. The 12 deaths from diphtheria showed a further increase upon the numbers in recent weeks, and included eight in Glasgow against seven and four in the two previous weeks. Of the seven fatal cases of scarlet fever three occurred in Edinburgh, and two both in Glasgow and in Aberdeen. The four deaths referred to "fever" included two both in Glasgow and in Edinburgh; three were certified as enteric, and one (in Edinburgh) as cerebro-spinal meningitis. The three fatal cases of measles occurred in Glasgow. The deaths referred to diseases of the respiratory system in the eight towns, which had been 41, 59, and 66 in the three preceding weeks, declined again last week to 59, and were three below the number in the corresponding week of last year. The causes of 15, or 3.5 per cent., of the deaths in the eight towns last week were not stated or not certified; in the 76 English towns the proportion of uncertified causes of death last week did not exceed 0.8 per cent.

HEALTH OF IRISH TOWNS.

In 22 town districts of Ireland, having an estimated population of rather more than a million, 581 births and 330 deaths were registered during the week ending Oct. 9th. The annual rate of mortality in these towns, which had been equal to 15.1, 16.9, and 16.2 per 1000 in the three preceding weeks, declined again to 15.1 in the week under During the 13 weeks of last quarter the annual death-rate in these Irish towns averaged 15.8 per 1000, whereas during the same period the death-rate did not exceed 11.9 in the 76 largest English towns and 12.6 in the eight principal Scotch towns. The annual death-rate last week was equal to 16.8 in Dublin (against 19.5 and 17.5 in the two previous weeks), 12.8 in Belfast, and 21.0 in Cork, and ranged in the smaller Irish towns from 3.9 and 5.1 in Waterford and Clonmel, to 19.7 in Kilkenny, 22.9 in Newtownards, and 32.7 in Drogheds. The 330 deaths from all causes in the 22 towns last week showed a decline of 24 from the number in the previous week, and included 37 which were referred to the principal epidemic diseases, against 42 in the previous week; these 37 deaths were equal to an annual rate of 1.7 per 1000, against rates last week from the same diseases not exceeding 1.3 in the English and in the Scotch towns. The 37 deaths from these epidemic diseases in the 22 Irish towns last week included 22 from diarrhoea, 10 from whoopingcough, three from "fever" (enteric), and one each from measles and diphtheria, but not one either from scarlet fever or small-pox. The 22 fatal cases of diarrhoa showed a decline of six from the number in the previous week, and included 11 in Belfast, five in Dublin, and four in Cork. The 10 deaths from whooping-cough included three both in Dublin and in Belfast, and two in Cork. Two of the three deaths from enteric fever occurred in Belfast. The 50 deaths referred to pneumonia and other diseases of the respiratory system last week in the 22 towns were fewer by six than the number in the previous week. The causes of seven, or 2.1 per cent., of the deaths in the 22 towns last week were not certified by a registered medical practitioner or by a coroner; in the 76 English towns the proportion of uncertified causes of death last week did not exceed 0.8 per cent., while it was equal to 3.5 per cent. in the eight Scotch towns.

VITAL STATISTICS OF LONDON DURING SEPTEMBER, 1909.

In the accompanying table will be found summarised complete statistics relating to sickness and mortality in the City of London and in each of the metropolitan boroughs. With regard to the notified cases of infectious diseases, it appears that the number of persons reported to be suffering from

" Including membranous eroup,

one or other of the nine diseases specified in the table was equal to an annual rate of 7.1 per 1000 of the population, estimated at 4,833,938 persons in the middle of the year; in the three preceding months the rates were 6.5, 6.4, and 5.0 per 1000 respectively. The lowest rates last month were recorded in Kensington, Chelsea, Hampstead, Stoke Newington, Holborn, the City of London, and Wandsworth; and the highest rates in Paddington, Islington, Bethnal Green, Poplar, Deptford, Lewisham, and Woolwich. Scarlet fever was much more prevalent than it had been in the preceding month; the greatest proportional prevalence of this disease was recorded in St. Marylebone, Bethnal Green, Poplar, Lewisham, and Woolwich. The number of scarlet fever patients under treatment in the Metropolitan Asylums Hospitals, which had been 2539, 2628, and 2329 at the end of the three preceding months, had risen again to 2717 at the end of last month; the weekly admissions averaged 394, against 353, 358, and 274 in the three preceding months. The prevalence of diphtheria also showed an increase compared with that in other recent months; among the various metropolitan boroughs this disease was propor-tionally most prevalent in Hammersmith, the City of Westminster, St. Pancras, Finsbury, Deptford, and Lewisham. The Metropolitan Asylums Hospitals contained 901 diphtheria patients at the end of last month, against 890 and 795 at the end of the two preceding months; the weekly admissions averaged 119, against 105, 107, and 83 in the three preceding months. Enteric fever continued to show an increasing prevalence; this disease was proportionally most prevalent last month in Islington, Holborn, Poplar, Battersea, Wandsworth, Deptford, and Greenwich. The number of enteric fever patients under treatment in the Metropolitan Asylums Hospitals, which had been 58, 60, and 55 at the end of the three preceding months, had risen again to 75 at the end of last month; the weekly admissions averaged 13, against nine, seven, and ten in the three preceding months. Erysipelas was proportionally most prevalent in Hackney, Finsbury, Shoreditch, Stepney, Poplar, and Deptford. The 22 cases of puerperal fever notified during the month included four in Wandsworth and two each in St. Pancras, Hackney, Camberwell, Greenwich, and Of the nine cases notified as cerebro-spinal meningitis three belonged to Lewisham and two to the City of Westminster.

The mortality statistics in the table relate to the deaths of persons actually belonging to the various boroughs, the deaths occurring in institutions having been distributed among the several boroughs in which the deceased persons had previously resided. During the five weeks ending Oct. 2nd the deaths of 5346 London residents were registered, equal to an annual rate of 11.5 per 1000; in the three preceding months the rates were 11.1, 10.2, and 10.5 per 1000. The lowest rates recorded last month were 6.1 in Hampstead, 8.6 in Paddington, 8.8 in Lewisham, 9.0 in Stoke Newington, 9.1 in Hackney, and 9.3 in the City of Westminster; the highest rates were 14.7 in Southwark, 14.9 in Finsbury, 15.4 in Bethnal Green, 15.8 in Poplar, 15.9 in Bermondsey, 16.3 in Holborn, and 18.0 in Shoreditch. The 5346 deaths from all causes included 803 which were referred to the principal infectious diseases; of these 30 resulted from measles, 27 from scarlet fever, of these of leading from measure, it from scales from diphtheria, 93 from whooping cough, 10 from enteric fever, one from ill-defined pyrexia, and 591 from diarrhea, but not any from small-pox or from typhus The lowest death-rates from these diseases last month were recorded in the City of Westminster, St. Marylebone, Hampstead, and Stoke Newington; and the nighest rates in Fulham, Finsbury, Shoreditch, Bethnal Green, Poplar, Southwark, Bermondsey, and Deptford. The 30 deaths from measles were 34 fewer than the corrected average number in the corresponding period of the five preceding years; this disease was proportionally most fatal in Shoreditch, Stepney, Poplar, and Lambeth. The 27 fatal cases of scarlet fever showed a decline of 19 from the corrected average number; the greatest proportional mortality from this disease was recorded in Bethnal Green, Poplar, Bermondsey, Lambeth. and Deptford. The 51 deaths from diphtheria were 13 below the average for the corresponding period of the five preceding years; among the metropolitan boroughs this disease caused the highest death-rates in the City of Westminster, Finsbury, Bermondsey, Lambeth, Camberwell, Greenwich, and

Lewisham. The 93 fatal cases of whooping-cough showed an excess of eight over the corrected average number; this disease was proportionally most fatal in Hammersmith, Holborn, Finsbury, Shoreditch, Bermondsey, Deptford, and Woolwich. The 11 deaths referred to "fever" were 26 below the corrected average number in the corresponding period of the five preceding years; of these 11 deaths, two belonged to Battersea and one each to nine other boroughs. The 591 fatal cases of diarrhoea were 447 below the corrected average; the greatest proportional mortality from this disease was recorded in Fulham, Finsbury, Shoreditch, Bethnal Green, Poplar, and Southwark. In conclusion, it may be stated that the aggregate mortality in London last month from these principal infectious diseases was 39 per cent. below the average.

Infant mortality, measured by the proportion of deaths under one year of age to registered births, was equal to 138 per 1000. The lowest rates of infant mortality were recorded in St. Marylebone, Hampstead, Stoke Newington, Holborn, Lewisham, and Woolwich; and the highest rates in Hammersmith, Shoreditch, Bethnal Green, Stepney, Poplar, Southwark, and Bermondsey.

THE SERVICES.

ROYAL NAVY MEDICAL SERVICE.

THE following appointments are notified:—Fleet-Surgeons: H. X. Browne to the Europa, H. B. Hall to the Lancaster, A. G. Wildey to the Venerable, on commissioning, and H. Holyoake to the Vivid. Staff-Surgeons: J. Mowatt to the Cressy, on recommissioning, and J. D. S. Milln to the Hawke. Surgeon: J. McCutcheon to the Venerable, on commissioning.

ROYAL ARMY MEDICAL CORPS.

The following tour-expired officers from India will proceed to England: Lieutenant-Colonel Forrest, Major Burnside, Major Thacker, Major Clark, Major Kiddle, and Captain Patch, by the Robilla, on Oct. 14th, from Bombay. Lieutenant-Colonel Blackwell, Major Jennings, Captain Pallant, Captain Turner, and Captain MacNicol, by the *Dengela*, on Oct. 27th, from Bombay. Lieutenant-Colonel Jencken, Lieutenant-Colonel Lequesne, Major Mudlison, Major Winter, Major K. Read, and Captain Vaughan, by the *Plassy*, on Nov. 5th, from Bombay. Lieutenant-Colonel Aldridge, Captain J. Richmond, Captain Harding, Captain Hole, and Captain Grant, by the Robilia, on Dec. 10th, from Karachi. Lieutenant-Colonel Nicholls, Lieutenant-Colonel Haines, Lieutenant-Colonel Nicholis, Lieutenant-Colonel Haines, Lieutenant-Colonel O'Callaghan, Major Innis, Captain Meadows, and Captain Ahern, by the *Dongola*, on Dec. 31st, from Karachi. Lieutenant-Colonel Wilson, Lieutenant-Colonel Rowan, Captain Carter, Captain Hildreth, Captain Osburn, Captain Wiley, and Captain Otway, by the *Plassy*, on Jan. 11th, 1910, from Bombay. Lieutenant-Colonel Cocks, Lieutenant-Colonel Elkington, Major Dalton, Captain Hall, Captain Fairbairn, Captain Arthur, Contain Wasson by the *Dufferin*, on Jan. 25th, from Captain Watson, by the Dufferin, on Jan. 25th, from Lieutenant-Colonel Swan, Major Anderson, Bombay. Captain P. Collins, Captain Hull, by the Rena, on Feb. 2nd, from Karachi. Lieutenant-Colonel Gordon-Hall, Major Grech, Captain Wetherall, and Captain Douglass, by the Robilla, on Feb. 11th, from Karachi. Lieutenant-Colonel Gordon, Major Luther, Captain Hardy, Captain Johnstone, and Captain Lewis, by the *Dongola*, on March 2nd, from Bombay. Lieutenant-Colonel W. W. Pike, Lieutenant-Colonel J. R. Stuart, Major T. MacDermott, Captain J. A. Turnbull, Captain F. J. Garland, Captain F. M. M. O'Omanney, Captain F. H. Noke, and Captain O. E. Cathcart, by the Plassy, on March 11th, from Bombay.

Captain M. F. Foulds has been appointed specialist in. advanced operative surgery for the Belfast District.

The undermentioned Captains, from the Seconded List, are restored to the establishment (dated Sept. 27th, 1909):—Francis J. Brakenridge and Raymond L. V. Foster.

INDIAN MEDICAL SERVICE.

Captain White has been appointed specialist in advanced operative surgery 8th (Lucknow) Division, vice Captain Browne, R.A.M.C. Lieutenant Russell, Brigade Laboratory, Bangalore, has been appointed specialist in the prevention of disease. The services of Captain Peebles are placed at the

disposal of the Punjab Government for employment in the analyst's department. Captain Nutt is temporarily posted to the United Provinces. Major Sutherland, principal and professor of medicine, Medical College, Lahore, is confirmed in that appointment; and Major Hugo, professor of surgery, Medical College, Lahore, is also confirmed in that appointment. Captain Hamilton is selected permanently for appointment in the Jail Department. Lieutenant-Colonel Baker and Major Pigon and Major Daniell retire from the Indian Medical Service.

SPECIAL RESERVE OF OFFICERS.

Royal Army Medical Corps.

Supplementary List, Lieutenant William M. Browne, from the Army Medical Reserve, to be Lieutenant, and to retain the rank and seniority which he held in the Army Medical Reserve (dated Sept. 23rd, 1909). John Charles Hall to be Lieutenant (dated August 18th, 1909).

TERRITORIAL FORCE.

Royal Army Medical Corps.

3rd London (City of London) Field Ambulance: Reginald Martin Vick to be Lieutenant (to be supernumerary) (dated July 23rd, 1909).

For Attachment to Units other than Medical Units.—Lieutenant Henry S. Walker to be Captain (dated April 1st, 1908).

Surgeon-Major James Harris Garcia Whiteford, from The Clyde Division (Electrical Engineers), Royal Engineers (Volunteers), to be Major, with precedence as in the Volunteer Force (dated April 1st, 1908).

Surgeon-Captain John Rowan, from The Clyde Division

Surgeon-Captain John Rowan, from The Clyde Division (Electrical Engineers), Royal Engineers (Volunteers), to be Captain, with precedence as in the Volunteer Force (dated April 1st, 1908).

THE COURSE OF INSTRUCTION AT HASLAR.

The course of instruction of the newly entered surgeons at Haslar was brought to a close on Oct. 6th by the distribution of prizes by Inspector-General Thomas D. Gimlette, C.B., R.N. The gold medal was gained by Surgeon A. A. Sanders of the University of Birmingham and the silver medal was awarded to Surgeon K. H. Hole of Guy's Hospital. These officers also took the first and second places respectively in the combined London and Haslar examinations. Three navy regulation pocket-cases—prizes for subjects in which instruction is given at Haslar—were awarded to Surgeon Sanders, Surgeon M. P. Fitzgerald, and Surgeon G. F. Syms. The following list shows the places gained by the combined marks of the London and Haslar examinations:—

			Marks.	1		Marks
A. A. Sanders	•••	•••	5178	J. Barrett		 4399
K. H. Hole	•••	•••	5152	G. A. Jackson		 4205
G. F. Syms			5051	W. Miller		 4167
H. F. Briggs		•••	4944	R. P. M. Roberts		
M. P. Fitzgerald	•••	•••	4873	A. G. Malcolm		
J. Hadwen		•••	4479	H. C. Devas	•••	 3749
J. S. Orwin	•••	•••	4423	H. W. Nicholls		

Of these 14 surgeons 10 possessed University degrees.

JOURNAL OF THE ROYAL ARMY MEDICAL CORPS.

The October issue of this journal opens with an introductory article on the Medical History of the South African War from the pen of Lieutenant-Colonel R. J. S. Simpson, O.M.G. Referring to the unjust criticisms of our sanitation during the war, the writer is of opinion that some were prompted by the parochial tendency of the average man devoid of imagination, others were the habitual, probably unthinking, criticisms which must always be expected, and others founded on mis-statements of fact. He believes that when the actual incidence of disease is considered in all its relations it will be found that the results, though not such as would be expected under our present improved organisation, are better than is generally believed. Lieutenant-Colonel T. Du B. Whaite writes some personal recollections of the early months of the South African War, which show that the risks run by the medical officer may often be as great as those of his brother in the fighting line. There is much exciting incident in the recol-lections, and the paper will be perused with interest. Among the other contents of the journal are some remarks on the treatment of gonorrhœa in Malta, by Major C. E. Pollock, R.A.M.C., chiefly with reference to the irrigation treatment, and a note on a method of securing

dressings without the use of bandages by means of gelatia. The writer, Major F. J. W. Baker, D.S.O., gives credit for the idea to Mr. B. G. A. Moynihan of Leeds.

THE NAVAL MEDICAL SUPPLEMENTAL FUND.

At the quarterly meeting of the directors of the Naval Medical Supplemental Fund, held on Oct. 12th, Sir C. J. Thomas, K. C. B., in the chair, the sum of £40 was distributed among the several applicants.

Correspondence.

"Andi alteram partem."

THE TREATMENT OF SYPHILIS BY INTRAMUSCULAR INJECTIONS OF INSOLUBLE PREPARATIONS OF MERCURY.

To the Editor of THE LANCET.

SIR,—We have read with interest Dr. G. Pernet's paper in THE LANCET of July 24th "On Intramuscular Treatment of Syphilis," and the "Critical Rejoinder" of Major H. C. French in your issue of Sept. 25th, as well as the reply of Dr. Pernet in your issue of Oct. 9th. Dr. Pernet is quite able to defend himself against the attack of the gallant major and does not require any support from us, but as the value of the method of treating syphilis by intramuscular injections of insoluble preparations of mercury is the matter at issue we feel we have some title to join in the conflict. In the past five years we have made a very extensive trial of grey oil in the treatment of syphilis both in hospital and private practice, and have administered several thousand injections, and we are firmly convinced that it is one of the most efficient remedies for syphilis at our disposal.

Every opponent of the use of intramuscular injections of insoluble preparations of mercury ransacks the literature to discover fatalities following their use; and every now and then, though at ever-increasing intervals, a fresh death is discovered. We have no hesitation in suggesting, in the light of present-day knowledge, that with ordinary care every one of these deaths might have been prevented. In some of the fatal cases recorded no details as to the doses administered were given, and in others there is no indication as to who administered the injections. These two points are of prime importance, for if no record of the dose is kept, and as in some hospitals in this country and in France untrained porters, dispensers, or orderlies are allowed to administer the injections, the wonder is that disasters do not occur more

frequently.

We would strongly endorse Dr. Pernet's statement, "That when intramuscular injections of grey oil are carried out with care and precaution complications do not arise." But we insist on more care and precaution than Dr. Pernet would seem to indicate, for in addition to examining the urine of patients for albumin we make periodical examinations to ascertain the rate at which the mercury is being eliminated by the kidneys. Only by doing so can we be sure that mercurial stasis is not occurring in the system, and our repeated examinations have enabled us to forecast with a tolerable measure of accuracy the number of weeks that elapse before the mercury disappears from the urine of a patient after a course of 12 or more injections. Deficient elimination leads us at once to diminish the dose or interrupt the treatment. We have also taken skiagrams of the Hg in the muscles and have estimated the number of days required for an injection to be completely absorbed. By taking these precautions, and by gradually improving our technique of administering injections, we have so far avoided all complications.

It has not been our experience that patients take only one injection and never come again. Some years ago we made statistics of the attendance at hospital of syphilitic patients before and after we began to employ intramuscular injections, and we found that patients treated by injections attended much more regularly than those treated by oral medication. We do not believe that "severe relapses are twice as frequent after injections as after the inunction or pill treatment," nor are we alarmed by the bogey of salivation. The severest cases

of salivation we have ever seen have been in patients treated with hydrargyrum cum creta, and we have seen patients with severe ptyalism produced by oral medication with syphilitic lesions that showed no sign whatever of yielding to the mercury which had been administered. Only a few days ago we saw a young man who had been taking 6 grains of hydrargyrum cum creta daily till marked gingivitis appeared without the slightest improvement in a large papular eruption on his face, and two years ago a young man, aged 30 years, came under our care who for five months had been taking 4 grains of hydrargyrum cum creta daily till he was salivated, and yet without any amelioration of a copious papulo-pustular syphilitic eruption which covered his whole body. An examination of his urine showed that though he was suffering from gingivitis he was eliminating mercury in a fair quantity by his kidneys. In spite of the condition of his gums we did not hesitate to begin intramuscular injections, and his ptyalism disappeared, and his eruption rapidly cleared up under injections of grey oil. He received at weekly intervals four injections of 14 cgs. of metallic mercury, and then 14 injections of 7 cgs. each, and then at intervals of a fortnight two injections of 10 cgs., and when last seen was in splendid health and had put on

We are surprised that Major French should lend the weight of his authority to the recommendation "that weekly insoluble injections of standardised grey oil should not ever be made for over six weeks, and in certain cases four weeks." Each case should be treated on its merits, and it may occasionally be advisable to give a patient such scanty treatment. But our experience has been that larger doses than his (Hg—grain 1) may be safely administered for 12 or more consecutive weeks, and we are prompted to wonder whether it is for this reason -viz., inadequate dosage-that Major French has been led to conclude that "Injections of insoluble salts of mercury have not the same curative action on syphilis in the early stages as inunction or hydrargyrum cum creta with opium." We have great confidence in intramuscular injections, and so have all our patients who previously have had experience of other treatment. Our experience has been that in medical circles the strongest opponents of the method are those who have never tried it.

We are, Sir, yours faithfully,

Liverpool, Oct. 11th, 1909.

STOPFORD TAYLOR, R. W. MACKENNA.

IS SNOW-WATER UNWHOLESOME?

To the Editor of THE LANCET.

SIR,—The theory that endemic bronchocele and cretinism are due to drinking snow-water is of considerable antiquity. Peter Lowe, in 1612 ("A Discourse of the Whole Art of Chirurgery," Lib. V., cap. 40), speaking of the causes of "The Tumour in the Neck or Cragg, called Broncocele or Hernia Gutturosa," says:—

Some are externall, and some internall, proceeding of a cold and humid ayre, drinking of evill water, as those who dwel in Pimount, and about the Alpes are much subject, because the most part of their drink is melted snow: it happeneth also by the retention of monethly courses in women, and Hemorrhoides in men, with great repletion of the melancholique humor in both sexes.

Lowe gives as his authorities, Chelmetius (Enchiridion Chirurgicum) and Arnaldus de Villa Nova. I cannot trace Chelmetius, but Arnaldus lived between 1235 and 1312 A.D. In his Breviarium (Lib. II., cap. 4. Ed. Basle 1575) he describes the swelling in the throat which Arabians call "Botium." In certain districts, for instance, in Coriphiane, he says that all men and women, or the greater part of them, are so affected, "forte ex natura aeris vel aquarum," and he adds that they cannot be cured, "nisi ad aliam aquam, vel aerem alium traducuntur." He does not, therefore, attribute the disease specifically to snow-water, but to some impurity in the air or water of the country.

John Evelyn, who in medical knowledge was usually up to date, refers in his diary for 1645 to the goitrons cretins whom he saw on his journey across the Alps.

"Their drinking so much snow-water," he says, "is thought to be the cause of it; the men using more wine are not so strumous as the women. The truth is that they area peculiar race of people, and many greate water-drinkers here have not these produces tumours; it runs as we say, in the bloud, and is a vice in the race."

The belief that goitre is caused by snow-water was held in the middle of the last century, for B. Nièpce ("Traité du Goitre et des Crétinismes," Paris, 1851) discusses and dismisses the view on the grounds that goitre and cretinism are not seen in high altitudes where only snow-water is obtainable. Perhaps this old doctrine that snow-water causes so terrible a condition as goitrous cretinism has led to the belief that snow-water is generally unwholesome. Like your other correspondents, I am curious to know whether there are any other grounds for the statement. Theoretically, snow-water, like rain-water, should be the purest of beverages, and it is interesting that rain-water has only recently been advocated as a remedy for goitre.

I am, Sir, yours faithfully,

LEONARD G. GUTHRIE.

Upper Berkeley-street, W., Oct. 12th, 1909.

PS.—"Snow-water," I assume, is the result of artificially melted snow.

THE HYPNOTIC TREATMENT OF MORPHINISM.

To the Editor of THE LANCET.

SIR,—In the treatment of drug addictions, as of disease generally, two totally opposite points of view may be adopted. By some a malady is looked upon as a something to be expelled by something to be taken. For headache, for instance, take phenacetin, for rheumatic pain take aspirin, for addiction to a given drug take a different drug. By others this routine prescription of medicines is held to be an encouragement of fetichism, and although we cannot always do without them it is maintained that they should only be prescribed exceptionally, that our main reliance should be upon preventive hygiene and dietetic measures, together in what are termed nervous ailments, with re-education of selfrestraint, character, and judgment. In THE LANCET of Oct. 2nd Dr. C. J. Douglas advocates the first of these plans in the treatment of morphinism. Whilst recognising the advisability of any treatment that can overcome habit in the case of an inveterate drug-fiend, incapable of recuperation of self-control, for the ordinary habitue who continues the use of morphia only because he has never been able to renounce it entirely, the "knocking-out" (as the Americans call it) of any drug addiction by a still stronger narcotic is, I would submit, very bad practice, and only exceeded in harmfulness by the method recommended by Sir William Whitla of keeping the patient in a state of alcoholic intoxication.

The temporary suppression of morphia by such a plan is not difficult, but such a suppression does not constitute a cure of habit, which can only be effected by a restoration of resolution to have nothing to do with narcotics. To teach that one narcotic is a panacea for another is, in my experience, to ensure future relapse, as an ex-habitué is sure to return in times of insomnia, irritability, or depression to what he has previously found preventive of suffering and will almost infallibly revert to the former condition. This is the opinion of Dr. Kellogg of Battle Creek, who insists upon the necessity for drug addicts of a return to a natural life, after a weaning without drugging. An equally eminent authority, Dr. T. D. Crothers, of Hartford, Connecticut, considers it is true that "drug restraint and narcotism are demanded imperatively in some cases," but his general experience is against it, and he says that "the substitution of even a mild narcotic early in treatment has been very unsatisfactory." "Insomnia," he adds, "should not be treated by hypnotics with any degree of regularity. The danger of another addiction is so great that it is unwise to use any of the hypnotics except for a brief time."

In his more recent essay on "Drugs and the Drug Habit"

In his more recent essay on "Drugs and the Drug Habit" Dr. Harrington Sainsbury looks upon the cure of addiction as almost entirely a question of re-education of self-control. "The kernel of the system," he says, "must be re-educational." If the patient is treated in an institution "self-restraint all round will be the key-note of treatment." This is his doctrine, and even as regards suggestion, hypnotic influence that takes the place of the will and which is the psychological correlate of hypnotic drugging is to be condemned. Hypnotism should not be used as counselled by Dr. Quackenbos at a recent congress as a substitute for the will. When, says Dr. Sainsbury, a patient is influenced in this way (and the same applies to hypnotic drugging), "his

reformation is not reform at all so far as he is concerned; he has been reformed from without, but inwardly he is wholly unregenerate. The will power must be led forth from its retreat." I should like to quote more fully from Dr. Sainsbury's learned and philosophical work, which should be read and meditated by every drug habitué, but those of your readers who are interested in this subject are, no doubt, acquainted with it already.

In conclusion, I would suggest that Dr. Douglas should make known through THE LANCET the after-history of his An easy cure without the intervention of personal effort is, in my opinion, a premium to renewed indulgence, but if the results claimed for this method have stood the test of time the publication of statistics of cases permanently cured will be most interesting.

I am, Sir, yours faithfully,

Oct. 5th, 1909.

OSCAR JENNINGS, M.D. Paris.

THE ANTITRYPTIC INDEX IN DIAGNOSIS.

To the Editor of THE LANCET.

SIR,-In your first leading article in to-day's issue of THE LANCET you allude to the non-specificity of the rise of the antitryptic index of the serum in malignant disease. This statement I can thoroughly endorse as a similar rise occurs in all of the general bacterial diseases so far examined, as well as in numerous conditions in no way associated with bacterial activity. The rise in antitryptic values in all these conditions I have long considered as possibly an index of the liberation of endocellular enzymes and other products owing to cell-destruction, and not merely of leucocytic products as your article suggests. In spite, however, of this non-specificity there is a limited range within which estimation of the antitryptic index is of the greatest diagnostic value in the differential diagnosis of cancer. In cases where the index is normal discoverable cancer can be almost positively excluded, six cases of 100 failing to conform to this rule. Since 94 of these cases showed a rise, the great value of the method lies in the demonstration not of rise but of absence of rise. Your article reflects only on the inverse of I have elsewhere shown how this mode of blood examination can, in conjunction with other clinical evidence, enable us to distinguish in many cases ulcer of the stomach from carcinoma of that organ, benign stenosis of the esophagus from malignant, the presence or absence of malignant mediastinal neoplasm, carcinoma mammæ from simple growths, benign cerebral tumours from malignant, and so on, and guide us as to recurrence. Hence, feeling as I do that, within the limits I have indicated, the estimation of antitryptic values is often of great service in diagnosis, as well as in other no less important directions, I venture to hope you will find room for this letter, and in so doing correct an impression of the worthlessness of the method that might arise from the perusal of your article.

Of all the numerous observations which I have published and of others as yet unpublished, I have not yet encountered a rise in antitryptic index which could not be confirmed by other methods of estimation undertaken by other observers. This holds true of the chemical method, the viscosity method, and that of electro-conductivity. I know of few blood estimations capable of corroboration by three distinct reliable I am, Sir, yours faithfully, E. C. Horr. methods.

Harley-street, W., Oct. 9th, 1909.

THE STANDARDISATION OF THE DIGI-TALIS SERIES OF HEART TONICS.

To the Editor of THE LANCET.

SIR,—On June 19th last there was published in THE LANCET a paper entitled "Proposed International Standard for the Physiological Assay of the Heart Tonics of the Digitalis Series," which I read before the Seventh International Congress of Applied Chemistry on May 31st, 1909. Since this paper was published I have deemed it wise to modify my definition of a heart tonic unit, and would be pleased if you will give publicity to the following statement, which is taken from a paper presented before the American Pharmaceutical Association on August 19th :-

Ten times the normal minimum fatal dose (M.F.D.) per gramme body weight of frog of the injected drug properly diluted for the standard preparation is considered as a heart tonic unit (H.T.U.); consequently the number of H.T.U. in a given evoic centimetre of a preparation of the heart tonics is equal to one-tenth of the quotient

obtained by dividing 1 by such M.F.D.—i.e., the number of H.T.U. in each cubic centimetre of fluid is one-tenth of the reciprocal of the M.F.D. To illustrate: If the minimum fatal dose of a given drug per gramme body weight of a frog is found to be equivalent to 0.01, then the given substance, assuming that it belongs to the group of heart tonics, would contain 10 heart tonic units: M.F.D. $\frac{1}{0.0\overline{1}} - 10 = 10$ H.T.U.

Definition.—A heart tonic unit (H.T.U.) is ten times the normal minimum fatal dose per gramme body weight of standard test frogs kept under proper test conditions. This rule can be applied to any of the heart tonics as a means of expressing such values in whole numbers.

the heart tonics as a means of expressing such values in whole numbers.

It is to be understood that the H.T.U. is a measure of toxic value, although such toxic values may be translated directly into therapeutic values, based on the U.S.P. average dose or any other dose, but there is great discrepancy in doses for the preparations which we expect in the near future to consider in another paper.

Proposed Standards for the Most Important Preparations of the Digitalis Series of the Heart Tonics.

Detroit, Michigan, Sept. 30th, 1909.

THE BENHAM TOP.

To the Editor of THE LANCET.

SIR,-Mr. C. E. Benham asks in THE LANCET of Oct. 2nd why, if my explanation of the phenomena of his top be the correct one, the green colour seen as the after-image of the black disc is not seen on the black lines. It should be noted that the red colour appears on the black lines corresponding to a portion of the retina which has not been stimulated at all because for that portion of the retina the black lines are only a continuation of the black disc. This seems to have been generally overlooked by those who have offered an explana-We have therefore to account for the red colour appearing on a part of the top corresponding to a portion of the retina which has not been stimulated by light. conditions are perfect for a contrast phenomenon, as there is a large mass of a dilute colour and a small dark portion. In many contrast experiments the induced colour so overpowers the inducing colour as to make it very difficult to ascertain the presence of the latter.

I am, Sir, yours faithfully, F. W. EDRIDGE-GREEN. Hendon, Oct. 7th, 1909.

VACCINATION WITH ATTENUATED LIVE CULTURES.

To the Editor of THE LANCET.

SIR,-Referring to my paper with the above title, published in THE LANCET of August 21st, I beg to draw attention to the fact that while typhoid vaccine (dead or alive) may be with advantage prepared with broth oultures, the dead or live dysentery vaccine and the mixed dysentery-typhoid vaccine should always be prepared with pepton-water cultures, as the inoculation of broth cultures of the Shiga-Kruse bacillus often induces a very painful infiltration at the seat of the I am, Sir, yours faithfully, inoculation.

Colombo, Sept. 16th, 1909.

ALDO CASTELLANI.

BIRMINGHAM.

(FROM OUR OWN CORRESPONDENT.)

The University.

AT a recent meeting of the Council the following resolution was unanimously passed:—

The Council desires to express its profound regret at the untimely death of Professor Foxwell, and to convey to Mrs. Foxwell and the members of her family its deep sympathy with them in their bereavement. It wishes to place on record its high appreciation of Professor Foxwell's services to the University as professor of therapeutics.

-Professor Jordan Lloyd has accepted the invitation of the Council to succeed Professer Bennett May as professor of surgery.—The vacancy caused by Professor A. Robinson's acceptance of the chair of Anatomy at the University of Edinburgh has been filled by the election of Professor Peter Thompson of King's College, London. Professor Thompson was educated at the Owens College, where he became demonstrator of anatomy. He was lecturer in anatomy at Middlesex Hospital, and in 1905 was appointed professor of anatomy at King's College. It is an interesting coincidence that in each of these appointments he succeeded Professor Robinson. Dr. Robinson's services as professor of anatomy and sub-dean of the medical faculty were greatly appreciated both by his colleagues and students, and much regret was expressed at his resignation.—The chair of Zoology, vacant by the death of Professor T. W. Bridge, F.R.S., has been filled by the appointment of Dr. F. W. Gamble, F.R.S. Professor Gamble also received his early training at the Owens College, where he has been assistant director of the zoological department and lecturer and examiner in zoology. He is widely known for his researches in connexion with the colour physiology of animals. - Mr. John Dale, M.B., Ch.B., B.Sc., has been recommended for election to the Walter Myers Travelling Studentship, and the Senate has approved of his holding the studentship at Hamburg. This is the first time this scholarship has been awarded since its foundation in 1901.

Hospital Sunday Fund.

The committee of this Fund is endeavouring to meet the difficulty patients often have in obtaining notes for those hospitals which require them. Out of 17 charities participating in the collections nine have a ticket system. On the committee's suggestion, three institutions, the General, Dental, and Orthopædic Hospitals, have agreed to issue circulars to subscribers, suggesting to the latter that if they were not prepared to undertake the distribution of their own tickets they should fill a form requesting the hospital authorities to hand them over to the City Aid Society. Thus there would be a centre where patients would be most likely to get the tickets they required, and so avoid the weary tramp from one subscriber to another. Negotiations are being carried on with the remaining hospitals which at present find some difficulty in participating in the scheme.

West Bromwich District Hospital.

The annual report, which has just been adopted, shows that the number of patients treated during the year ended June 30th was in the general department 780, and in the eye department 116, an increase of nine and seven respectively over the previous year. The general out-patients numbered 9566, an increase of 1242, and in the separate eye department there were 2751 out-patients, a decrease of 89.

LIVERPOOL.

Oct. Ilth.

(From our own Correspondent.)

University of Liverpool: Interesting Blue-book.

THE Blue-book just issued from the Board of Education containing reports from the universities and university colleges in Great Britain which participated in the Parliamentary grants during the year 1907-08 contains interesting matter in regard to the University of Liverpool. There were 1004 day students, of whom 294 were women, while there were 595 persons attending the University evening courses, of whom 97 were women. About 78 per cent. of the total number of day students entered from public secondary and private schools, 21 per cent. coming from pupil-teacher centres and primary schools. A students union is in course of erection on a site adjacent to the University which will provide accommodation for men and women students

in different wings. The portion of the union building to be first erected will cost about £10,000. A students' magazine is published fortnightly during the terms. There are three terms of 11 weeks each, but the evening-class terms are of ten weeks' duration. Two halls of residence have been established in connexion with the University under the control of resident warden and separate committees, one for men and the other for women. The financial statement shows the receipt of Government grant, £13,000; city of Liverpool, £10,000; Lancashire county council, £1100; Cheshire county council, £300; Birkenhead council, £500; fees from students, £17,900; interest on investments, £10,450; special donations, £5000. The endowments represent over £300,000 and sites and buildings £350,000.

Drink and Insanity: Cost of Institutions.

Two interesting reports were presented to the city council at its recent meeting, one by the representatives of the council on the Lancashire Inebriates Board, and the other by the representatives of the council on the Lancashire Asylums Board. The reports show that more female inebriates are becoming chargeable to the public funds and lunacy is increasing alarmingly. The amount paid by the Liverpool Watch Committee towards the expenditure of the inebriates board since its inception in 1902 was £15,216, an average of about £2000 a year. The total sum paid to the asylums board for the year 1908-09 in respect of lunatics sent from the parish of Liverpool, the township of Toxteth Park, and such portion of West Derby as is within the city of Liverpool, was a little over £100,000; in addition to which the Liverpool corpora-£34,543. Out of the total patients under care in the county asylums during 1908, over 24 per cent. have been sent from Liverpool. Great difficulty is now experienced in accommodating the patients in the existing five county asylums and the cry is for more asylums. Since the opening of the reformatory for inebriates at Langho, near Blackburn, in April, 1904, 78 persons have been committed from Liverpool. The average number of convictions against Liverpool inmates at present in Langho is 21. The report states that one woman from Lancaster had been convicted 149 times.

Liverpool and Vaccination.

The anti-vaccination movement in Liverpool does not appear to find much favour with the sensible inhabitants of the city. At a meeting of the select vestry held on Oct. 5th it was reported that for the half year ending December, 1908, 2452 births were registered in the parish of Liverpool, and of these 2044 were successfully vaccinated; one child was returned as insusceptible to vaccination, and 11 children were returned as not having been vaccinated owing to the conscientious objection of their parents. The remainder of the children had either died or been removed from the parish before the period allowed for vaccination had expired or had the operation postponed by medical certificate. None of the children had been reported as having suffered from small-pox.

The Liverpool Crematorium.

The crematorium at Anfield has now been acquired by the corporation of Liverpool, and the municipality is desirous of popularising the institution. For the first nine months of this year there were 37 cremations, as compared with 34 during the whole of the year 1908. The medical officer of health, Dr. E. W. Hope, and the city engineer are at present preparing a report on the subject of cremation, which will, no doubt, take into account the progress of cremation in other towns in this country as well as on the continent. Hopes are now entertained that, under the change effected, the fees, which at present are above the reach of many, will be materially reduced. Dr. Richard Caton, formerly Lord Mayor of Liverpool, has been elected the chairman of the new crematorium subcommittee.

Munificent Gift to Bury.

Mr. Thomas Aitken of Bury has, I hear, given Holcombe Hall and the grounds adjoining to the Bury and District Joint Hospital Board for a hospital for the treatment of phthisis. The gift is valued approximately at £30,000.

Liverpool School of Tropical Medicine.

Mr. Wilfred Parsons, who was selected to take charge of a branch of the school in Grand Canary, sailed for Las Palmas on Oct. 8th.

Oct. 12th.

WALES.

(FROM OUR OWN CORRESPONDENT.)

Phthisis in Cardiganshire.

THE high death-rate from phthisis prevailing in Cardiganshire has frequently been commented upon. In the last published annual report of the Registrar-General, that for 1907, it is stated that in the five years ending 1907, of the 14 counties in England and Wales suffering the highest fatality from phthisis not fewer than seven were Welsh, and among these, Cardiganshire experienced a death-rate nearly double the average for England and Wales. The actual rates were 1.17 per 1000 in the whole country and 2.30 per 1000 in Cardiganshire. In the summary of the reports of the medical officers of health, which has just been presented to the Cardigan county council by Mr. Walter Ll. Davies, it is stated that in 1908 the phthisis death-rate in the whole county was 2.03 per 1000. Contrary to what is found elsewhere, the death-rate in the urban districts (1.7) was lower than that in the rural (2.1). In Newquay urban and Lampeter rural districts the rate was 0.8 per 1000. In no other district was it below 1 per 1000. In five districts it was over 2 per 1000 and in the town of Cardigan it was as high as 3.1 per 1000. This deplorable death-rate from a preventable disease is attributed by some of the medical officers of health to the dietary of the people, by others to the dampness and dilapidated conditions of many of the dwellinghouses, while one considers that the high fatality is influenced by the return home of persons infected elsewhere. The West Wales Sanatorium at Alltymynydd is thought to be doing something in the way of reducing the incidence of the disease, but Mr. Davies considers that the first step to take in fighting the scourge is to adopt a system of compulsory notification, together with adequate arrangements for the free bacteriological examination of sputum. There is ample evidence in the reports of the district medical officers of health that the housing conditions in the county are responsible for a large amount of ill-health among the inhabitants. In Aberayron, for example, there are damp houses built up against the live earth, without ceilings, without rain-water gutters or damp courses, and insufficiently lighted and ventilated. In three localities in the Aberystwyth rural district the houses are described as being in a dilapidated condition and hardly fit for human habitation. In many of the houses in Tregaron the only fresh-air inlet is said to be the door, and after making a house-to-house inspection the sanitary inspector found that among 720 dwellings there was no bedroom fireplace in 260, while at 230 there was no privy accommodation.

Medroal Officers' Focs.

At the last meeting of the Aberystwyth board of guardians (Cardiganshire) on Monday objection was made to the payment of £1 2s. 6d. to the district medical officer, Mr. G. R. E. Bonsall, for the quarterly visit of nine imbeciles under his charge, on the ground that one of the paupers included in the list was examined by another medical officer (Dr. J. A. Rees), who had failed to satisfy himself that the woman referred to was a lunatic. The clerk explained that there was undoubtedly a distinction between lunatics and imbeciles, and before any of them could be sent to the asylum or workhouse an order must be obtained adjudicating them lunatics under the Act. The second medical officer was called in for the purpose of certifying whether the woman could be removed into the workhouse. was agreed to pay the bill. Objection was also made to the payment of a fee of £1 1s. charged by Dr. A. Bassett Jones for assisting Mr. Bonsall in administering chloroform in the workhouse. During the discussion it was stated that the guardians had decided that all communications between them and Mr. Bonsall, who is also the workhouse medical officer, should be made in writing. The fee was objected to on the ground that the guardians had agreed, after ascertaining the fees allowed in other unions, to allow a fee of 10s. 6d. only for extra medical attendance. allowed to speak, Mr. Bonsall said he would like to know what his position would be, as he did not think any medical men in Aberystwyth, or elsewhere, would give him assistance for less than £11s. He positively declined to administer chloroform alone in instrumental cases, and it was unreasonable to expect him, when his fee was only 15s., to pay £11s.

from his own pocket for assistance. The guardians decided to allow a fee of 10s. 6d. subject to the Local Government Board's approval.

Pontyprol Water-supply.

At the last meeting of the Pontypool urban district council the medical officer of health (Mr. S. B. Mason) reported that owing to the large number of cases of diarrhœa and enteritis he had had a sample of the water examined and with not very satisfactory results. Two years ago a serious epidemic of typhoid fever in Pontypool and the adjoining districts was attributed to the water supply.

SCOTLAND.

(FROM OUR OWN CORRESPONDENTS.)

Edinburgh Post-Graduate Course.

With the last week of September the Edinburgh Post-Graduate Course was completed, and the senior members of the medical school who had not shared in the work of the course begin to return from holiday and to take up their official duties. The course was again a gratifying success. It was attended by about 90 doctors of both sexes drawn from many parts of the world, who had received their student training in many different schools. The entrants worked with extraordinary zeal from morning to night and were pleased at the provision supplied by many classes. What seemed to please them especially was the number of things they could do in the small number of weeks embraced in the course.

Opening of the Winter Session at the University of Edinburgh.

The winter session of the medical faculty of the University of Edinburgh began officially on Oct. 1st, and, as was anticipated, the attendance of students was not large. The new professor of anatomy, Professor Arther Robinson, however, delivered his introductory lecture on that day in the McEwan Hall and got a very hearty reception. He spoke of "Anatomy from 1705 till 1909." On Oct. 4th, Professor Alexis Thomson delivered his introductory lecture as professor of systematic surgery. This address was also delivered in the McEwan Hall, and the new professor was accorded a hearty welcome. He dealt with the history of surgery.

Changes in the Edinburgh Extramural School of Medicine.

The main changes in the extramural school of medicine have been in the department of surgery. Mr. James Hodsdon, F.R.C.S. Edin., has resigned the lectureship in systematic surgery at Surgeons' Hall and has been succeeded by Mr. Henry Wade, F.R.C.S. Edin.; Mr. A. Miles, F.R.C.S. Edin., has resigned his lectureship at the New School and has been succeeded by Mr. J. W. Struthers, F.R.C.S. Edin. It is a fact worthy of note that at the present time not a single ordinary full surgeon to the Royal Infirmary is lecturing on systematic surgery; all the lecturers are assistant surgeons either at the Royal Infirmary or at Leith Hospital, and are consequently classed as juniors. This seems to be an unprecedented state of affairs.

The Medical Staff of the Eastern Hospital, Dundee.

The question of the medical staffing of the East Poorhouse Hospital was discussed at a recent meeting of the Dundee parish council. Various proposals were brought forward, but eventually it was unanimously decided that the matter should be referred back to the poorhouse committee. A letter was read from Dr. Eric A. Thomson tendering his resignation of the post of resident medical officer at the East Poorhouse Hospital.

Dundee Town Council and the Treatment of Phthisis.

The Dundee town council on Oct. 8th had the question of phthisis again under discussion. A subcommittee of the public health committee recommended compulsory notification, isolation of advanced cases, and negotiation with the sanatorium authorities for the acquisition of 20 beds in the institution. In support of these proposals it was pointed out that voluntary notification and the dispensary had been failures. The former had failed because of the inadequacy of the means available for securing complete and perfect notification, and the dispensary had failed because it was altogether

inadequate for the treatment of cases which they knew to exist. Compulsory notification, so far as Dundee was concerned, would cost £50 per annum at the most. In opposition to the proposals it was argued that compulsory notification would mean labelling as consumptives 2000 people, and would practically throw these people out of work. The committee's proposals were rejected by 15 votes to 9. It was then moved as an amendment that the recommendations be adopted, except the last, that referring to the 20 beds in the sanatorium. This was defeated by 13 votes to 10. It was then moved that compulsory notification be adopted and that consideration of the other proposals of the subcommittee be dropped, but this was defeated by 13 votes to 10. A proposal that provision of a simple nature be made at King's Cross Hospital for advanced cases was carried by 19 votes to 5, and the meeting, which had lasted for four and a half hours, then terminated.

New Professors.

A meeting of the Senatus of the University of Aberdeen was held at Marischal College on Oct. 5th, Professor W. Stephenson presiding. Dr. John Marnoch presented his commission by the Crown in his favour as professor of surgery in room of Professor A. Ogston. A cordial welcome was extended to the professor by the chairman. Professor Marnoch afterwards signed the roll and took his seat as a member of the Senatus. On the following day the winter session of the University of St. Andrews was opened, when Dr. J. C. Irvine was installed to the chair of chemistry in the University in room of Professor Purdie. Principal Sir James Donaldson administered the oath, and the new professor received the right hand of fellowship from his brother professors.

Medical Inspection of School Children: The Aberdeenshire Scheme.

The adjourned conference between the members of the secondary education committee and representatives of the school boards of the county of Aberdeenshire, called to consider the scheme prepared by the county committee for the medical inspection of school children was held in Aberdeen on Oct. 9th. Sir Arthur Grant of Monymusk moved:—

That the secondary committee be most respectfully asked to take back the present scheme, to reconsider the matter both from the pecuniary and other points of view, and to bring forward an amended scheme or another scheme.

The motion was unanimously agreed to and the meeting terminated.

Oct. 12th.

IRELAND.

(FROM OUR OWN CORRESPONDENTS.)

Prevention of Cruelty to Children: Infantile Hygiene in Ireland.

READERS who are specially interested in the all-important subject of the treatment of children and who have listened with attention to the cascade of jeremiads on the subjects of "race suicide" and "physical deterioration," have taken special notice of an address delivered a few days ago to the Clonmel branch of the Society for the Prevention of Cruelty to Children by Mrs. Schooling, a member of the central executive of the organisation. As the speaker lives and works in England she was able to speak with authority, and her hearers had some substantial reason for gratification when she told them that the parents of Irish children treated children more affectionately than did the English. In none of the cases which had been investigated in the district during the past year had anything worse than neglect been brought to light, and after a prolonged and varied experience she did not think that she had ever had such a clean list in England. In Ireland they did not find the continuous and systematic brutality of treatment of children which was so frequently and so painfully revealed on the other side of the Channel and on the continent. The Irish might be hot-tempered (which was not a bad fault), and they might have other faults, but they were not brutal to little children. She had seen in Dublin, Cork, Bandon, and other places, children who, though they might be dirty and ill-clad, were still healthy and strong looking; and one would never see amongst them little wizened faces—the little old men and women children—one saw in English cities. Whilst we were very much pleased to receive this tribute of important expert testimony from a visitor coming from English districts, and with long experience therein, we fear that the contrast of the relationship between parents and children on the two sides of the Irish Channel holds good far more in the country than in the city. The children in our cities do not display the racial vigour of which Mrs. Schooling has said such complimentary things.

The Temperance Movement in Ireland.

The Father Mathew Memorial Hall was opened in 1891 by Dr. Walsh, the Catholic Archbishop of Dublin, who had laid the foundation-stone of the building in 1890, the centenary year of the Irish Apostle of Temperance. The gratifying history has since been that of a continuous increase of the roll of membership. An extension wing of the hall was opened early this month, and the vitality of the temperance movement is also testified to by its patronage in the highest places, as well as by the construction of a horse-drawn caravan which conveys pure and pasteurised milk around the roads and avenues of Phoenix Park. The "Temperance Drink Caravan" is another fruit of Lady Aberdeen's interest in the material prosperity and physical comfort of the Irish people, and to hear a country cattle-driver come to town for the day, bawling out at the top of his voice, "Will you, plaize, hand me out a glassful o' that paralysed milk as quick as ye can, for I'm very droughthy," shows the widespread good that is being done.

Royal College of Surgeons in Ireland.

Dr. A. Campbell Geddes, assistant professor of anatomy, Royal College of Surgeons in Ireland, has been elected professor of anatomy in room of the late Professor A. Fraser. Professor Geddes was formerly assistant to the late Professor D. J. Cunningham in the University of Edinburgh.

" Christian Soicnoe" in Ireland.

The estimate of "Christian Science" which has been arrived at by the Irish people has been formulated in the Freeman's Journal. A fact which can hardly fail to interest all readers of THE LANCET is that the widely read Irish newspaper was originally founded by a Dublin apothecary, and a well-known feature of its policy remains, its sympathetic attitude towards the medical profession. Research Defence Society and its able exponent, Mr. Stephen Paget, have rarely been exhibited in a better setting than in the article referred to, which bears the title of "Unchristian The text was furnished by the appearance of Mr. Paget's recent "work exposing the methods of the pseudoscience that has annexed the name of Christianity as a covering to its callous obstinacy and folly," and the quotation shows that the writer of the article minces no words. He alludes to persons who are "lacking the sound basis of a training in logic or in the principles of evidence, who because of that lack find in their education their worst enemy. Opened, by what they call their education, to the attraction of intellectual dabblings, anxious to have intellectual sensations, unable to see life as a concrete whole, supremely able to ignore half its facts if only they get a pseudo-intellectual leading towards mystic fancyings, they expose themselves to follies which the uneducated and the well-educated alike reject with loathing. These people, the crudely emotional, the entirely credulous, unbalanced, half-blind, seem to be one of the great unforeseen dangers of modern society." The view here so forcibly enunciated exposes one of the painfully conspicuous results of education at its present point. I regard the publication of this article at this juncture as one of the specially hopeful prognostics of the future of medicine in the new National University.

Belfast Charity Organisation Society.

The Charity Organisation Society in Belfast has for some time been trying to get the various hospitals and other eleemosynary societies in that city to agree to a proposal to collect subscriptions for the various philanthropic bodies by means of a schedule issued by a central agency. The scheme has, notwithstanding great opposition, been vigorously pushed, with the result that of 56 local institutions whose opinion was asked on the matter by the executive committee of the Belfast Charity Organisation Society, 17 promised to support the scheme were it adopted, 22 declined to fall in with it, while 17 have either not

replied or have replied indefinitely. The executive committee consider now that the number of institutions prepared to support the scheme is quite sufficient to warrant a beginning, and they recommend that a central scheme should be proceeded with at once, with a view to issuing the first appeal pamphlet and schedule in the beginning of next year. The Mater Infirmorum Haspital and the Royal Victoria Hospital did not see their way to join in the scheme.

Londonderry Fever Hospital.

At a meeting of the Londonderry board of guardians, held on Oct. 9th, replies were received from the medical officers of the workhouse in reference to complaints made recently by the staff nurse. It was agreed that the telephone to the hospital did not work well, but one of the medical officers pointed out that he had frequently reported the matter to the guardians. As regarded want of assistance, it was explained that when the nurse complained there were only 14 patients in the fever hospital, of whom nine were convalescent. The medical officer thought that two nurses, one for day and one for night duty, and three able-bodied women to do the rough work were sufficient. The lectures given to the probationer nurses were delivered when the staff-nurse was on duty in hospital and did not need the use of her sitting-room. As to the question of personal disinfection the medical attendant claimed to be a better judge of that matter, and he did not think the guardians need be alarmed. It was decided by the board of guardians to order a new telephone, and by 12 to 3 votes a motion was passed marking both letters as satisfactory, that is, the complaint of the nurse and the reply from the medical attendants.

Oct. 12th.

PARIS.

(FROM OUR OWN CORRESPONDENT.)

Naval Medical History Sheets.

THE Under-Secretary of State for the Navy has directed that every sailor shall be provided with a medical history sheet, on which shall be entered all particulars relative to the man's height, weight, chest measurement, vision, and hearing, and which shall accompany him throughout his progress in the service. The surgeonmajors or hospital medical officers shall enter on it the results of such examinations as they make, as well as references to attacks of illness, hospital treatment, and convalescence. This record will be passed on, enclosed in a sealed envelope, from one medical officer to another by the director of the service de santé or by the officer commanding the depôt or ship in question. When a man has been treated for an illness of a confidential nature it shall be denoted only by the number contained in the nomenclature used for that purpose. Wounds or accidents which may entitle a man to a pension are to be very precisely described in this record.

Raperimental Transmission of Exanthematic Typhus by the Agency of Lice.

At a recent meeting of the Academy of Sciences M. Charles Nicolle, M. Comte, and M. Conseil said that some experimental observations on which they had been engaged seemed to show that the pediculus corporis was the principal agent in the transmission of the pathogenic virus of exanthematic typhus. Pediculi corporis collected from the human body and kept without food for eight hours were placed on a monkey suffering from this disease; they were then transferred to a healthy animal of the same species which eventually became infected. These observers therefore believed that for the prevention of exanthematic typhus it would be desirable to get rid of the parasites which infested alike the body, clothing, and bedding.

The Prevention of Cholera.

The Minister of Marine has sent to all the ports and to the officers in command of squadrons a telegram stating that in the event of cholera being notified in any port or squadron he is to be informed of the fact by telegram. During the recent epidemics in St. Petersburg some use was made of a specific serum discovered at the Pasteur Institute in Paris and the Minister of Marine has directed that it shall be employed in the navy. The quantity in the possession of the

institute being very small, it has been arranged that when the existence of cholera is telegraphed to the Minister a representative of the institute shall proceed to the scene of the outbreak for the purpose of conducting the serum treatment.

The Third Congress of Medical Practitioners.

The Third Congress of Medical Practitioners will be held in Paris at Easter in 1910, and some of the subjects to be brought forward at the meeting will include the collective results of replies to specific inquiries. The organisers of the congress appeal to the courtesy and professional fellowfeeling of the secretaries of medical associations in the hope that they will assist these investigations by either personally replying to the lists of questions which will be sent to them or by giving the names of members who may be willing to do so. In consequence of the information thus supplied the speakers who will introduce the subjects will not confine their remarks to their personal opinions, but will in addition give prominence to the ideas communicated to them by their correspondents, and the interest which these addresses will possess for the medical profession will be greatly increased. The subjects of the official programme will include the illegal practice of medicine, medical aid associations, hospital treatment of the poorer classes, hospital administration, increase of medical fees, and the application of the statutes relative to public health.

Prize Essays on the Punishments of Children.

The Société d'Hygiène de l'Enfance is offering prizes for essays on the Punishments of Children. Essays will be received up to Dec. 31st, 1909. They must not have been already published and must be written in French, German, English, Italian, or Spanish. They will not bear the author's name, but will have at the top a motto which will be repeated on a sealed envelope containing the author's name and address. Authors disclosing their identity will be excluded from the competition. The essays will not be returned even though they do not gain a prize; they become the property of the society and may not be published by their authors. The society reserves the right of extracting from the best of them the materials for a pamphlet. The prizes, which will be awarded at the annual public meeting of the society in 1910, will consist of gold, silver-gilt, silver, and bronze medals. The essays should be sent before Dec. 31st, 1909, to the President of the Société d'Hygiène de l'Enfance, 10, rue Saint Antoine, Paris.

Oct. 12th.

BERLIN.

(FROM OUR OWN CORRESPONDENT.)

Remarkable Case of a Morbid Craving for Glycerine.

A CURIOUS case of what might be called the glycerine habit is described in the Deutsche Medizinische Wochenschrift by Dr. Schmey of Beuthen, in Silesia. Instances of acute poisoning by glycerine have been described by a few observers. Professor Nothnagel has recorded one in which the symptoms included severe colic and syncope. Professor Lewin has remarked that the symptoms were sometimes very like those of cholera nostras together with a state of nervous excitement similar to that of alcoholic intoxication. The case recorded by Dr. Schmey is the first one of habitual consumption of glycerine amounting to a morbid habit that has been described in medical literature. The patient was a young man who, according to the statement of his mother, had contracted the habit of taking glycerine internally in great quantities. He had attended a college in a neighbouring town, but as his obsession had become known to his mother she took him home and consulted Dr. Schmey. The patient did not show any peculiar symptoms; he was rather pale, the liver was somewhat enlarged, the urine did not contain either albumin or sugar, the bowels were regular, and his appetite was tolerably good since his return home. There were slight nervous symptoms, including dermographia and an increase of reflex irritability. He only complained of general debility and weakness. He admitted that he had been in the habit of taking glycerine for the previous three months, having heard that it was a useful remedy for nervous pains. He had at first taken 100 grammes per day, but he had After these great doses he had afterwards felt a certain sleepiness, so that he used to go to bed. Dr. Schmey saw the patient on only one occasion, after which all offers of attendance or advice were refused; the mother, however, told Dr. Schmey that her son, who formerly had been good-tempered, had become impatient and irascible and that he would even steal money from his mother and sister to buy glycerine. The mother did not follow the advice of the medical man to have her son sent to an institution for medical treatment. Dr. Schmey remarks that the glycerine seemed to have produced no other ill effect than a slight enlargement of the liver. It was not easy to understand why the young man took such great quantities of glycerine; obviously it had the effect of producing in him certain pleasurable sensations similar to those of alcoholic intoxication, as mentioned by Professor Lewin.

Illegitimacy in Germany.

Dr. Fischer of Karlsruhe in Baden has drawn attention to the fact that Germany, Austria, and Sweden have a very high proportion of illegitimate children; whilst in Switzerland, England, and the Netherlands only 4 per cent. of the births are illegitimate the corresponding number for Germany was 8.5 per cent., and in some parts of Germany, such as Bavaria and Saxony, it was even 13.4 per cent. He said that illegitimate children were a danger for the community, not because of their illegitimate birth itself but because they were badly fed and were liable to contract and to spread infectious diseases; they were, as a rule, in a worse state of nutrition than legitimate children because they were more seldom suckled. But apart from their physical condition they were on an average inferior in respect of their morality, statistical researches having shown that the proportion of illegitimates among the prisoners in the penitentiaries of Würtemberg was 27 per cent., whilst in Berne it was 14 per cent., and this large proportion was reached notwithstanding the high mortality of the illegitimate. To ascertain the causes of the great number of illegitimate children the condition of the mother was of importance. In Berlin it was stated that the number of unmarried mothers under 20 years of age was nearly double that of married mothers, being 2000 for the unmarried and 1116 for the married. In the Grand Duchy of Hesse of 35,563 married mothers only 1 per cent. were under 20 years of age, but of 2756 unmarried mothers 21.8 per cent. were under 20 years of age. It has been alleged that for the improvement of the race it was desirable that women should become mothers while comparatively young, but this was only true to a certain extent, the limit being 20 years; women under that age produced, as a rule, weaker children than older women did. Dr. Fischer concludes from the above facts that in the majority of cases the young women become mothers against their will, sometimes perhaps through frivolity, but in a great many cases certainly through imprudence. It must, according to him, be a matter for careful consideration whether a remedy for this lamentable state of affairs was to be sought in legislative measures or in instruction in sexual matters as proposed by many medical men, hygienists, teachers, and philanthropists. Oct. 11th.

SWITZERLAND.

(FROM OUR OWN CORRESPONDENT.)

Hygiene at Zürich Municipal Schools.

THE annual report of the municipal schools of Zürich for 1908 has just been published. The number of school children was 23,385. Of 3652 who were examined for the new school year 288 (or 7.8 per cent.) had to be refused owing to bodily (228) or mental (60) deficiencies. Owing to infectious diseases in their homes, 1462 children were temporarily forbidden to attend school (mostly home cases of scarlet fever and diphtheria). The ophthalmological examination of these school children showed 22·1 per cent. to have anomalies of vision, half of which (11·4 per cent.) referred to astigmatism. This year 2627 scholars of the sixth class (aged 11 to 12) were also examined. 24·7 per cent. had visual defects (astigmatism 8·7 per cent., myopia, 5·7 per cent.). The aural examination refers to 3606 children. 300 of these (8·3 per cent.) were affected. 200 cases of catarrh of the Eustachian tube were diagnosed, the majority of which (169)

had adenoids. The dental surgeon, who entered on this ew sphere of action on May 1st, 1908, had an immense amount of work in the investigation of the teeth of 3652 new scholars. Caries is very prevalent in Zürich, and only 45 (1·5 per cent.) had absolutely healthy teeth—a truly appalling fact. With due assistance he treated over 3000 patients. 27 children were given a course of treatment for stammering. The schoolmasters and parents must continue the good work begun if definite good results are to be obtained. Thousands of children joined in the sports classes arranged officially, and 1208 passed successful examinations after taking a swimming course. An investigation showed that 63 per cent. of all the scholars of the sixth class could swim. I may mention that all classes of society send their children to these municipal schools, a small minority (perhaps 200 only) attend private schools, and some 400 so-called Church schools.

Accidental Deaths in Switzerland.

The Federal Statistical Department in Berne publishes statistics for the quinquennium 1901 to 1905, of which an extract is of general medical interest. The total number of fatal accidents has increased during the last 20 years from 7949 to 10,308, or from 266 to 343.5 per 10,000 inhabitants. Falls occasioned 2608 deaths (75 being due to mountain accidents), carriage accidents 508 (motor-cars 10, bicycles 28), railway and tram accidents 410 (trams 65), bites 8, gunshot wounds 141, poisoning with berries 28, with mushrooms 19, with acids 24, with alkalies 21, with arsenic 5, with phosphorus 8, acute alcohol poisoning 34, meat poisoning 39, medicinal poisoning 29, death under anæsthetics 37, from insect stings 33, from snake-bites 2, after infection from slight wounds 232, drowning in lakes 1187, in ponds, &c., 501, poisoning by carbonic oxide 90, other gases 14, suffocation in bed 121, and from other causes 156, deaths from avalanches 56, from frost-bite 177, from burns 976, from sunstroke 60, from lightning 46, from electric currents 92, from hunger 5, and from undetermined cases 63.

Zürich, Oct. 6th.

ITALY.

(FROM OUR OWN CORRESPONDENT.)

Award of the De Vincenzis Prize in Ophthalmology.

AT the "Congresso Internazionale di Oftalmologia," held at Naples in April last, it was announced that a special prize had been instituted in that department of medicine to be called the "Premio di Oftalmologia De Vincenzis," in memory of the life and work of that great pioneer. The prize, consisting of seven gold medals, is open to foreign and to national competitors, three of the medals to be awarded to the former and four to the latter. The award of the national medals is entrusted to specialists holding chairs in the several seats of learning throughout the kingdom, and one has just been conferred on Dr. Gaetano Sampieri of the Army Medical Department for his essay bearing the title "Dei Linfatici delle Palpebre e loro Vie di Reflusso" ("The Lymphatics of the Palpebræ and their Channels of Reflux").

Epidemic of Small-pow on the Neapolitan Riviera.

While a friendly controversy is now being waged between the medical schools of Paris and Turin as to whether France or Italy had the honour of being the first to practise the Jennerian prophylactic; and while there has just been unveiled at Frascati a statue of Cardinal Massaia, the great Capuchin missionary, to commemorate (inter alia) his successful introduction of vaccination among the savage tribes of Western Abyssinia-an innovation which marvellously facilitated his Christianising efforts prolonged over 35 years—we are having fresh proof of the persistence of small-pox in various provinces of the Italian kingdom, the outbreak at Parma having, at a short interval, been followed by a still more formidable visitation at Salerno. For two months, it seems, this much-frequented sun-trap on the Neapolitan Riviera has witnessed an epidemic of variola, of which 60 cases have been reported and 20 with fatal results. As recently as Sept. 27th the municipality proceeded to energetic prophylactic measures and the official vaccinators were on active duty accordingly. But the people forcibly resisted. The incident demonstrates the difficulties with which public hygiene has to struggle in Italy, and must be attributed, in the last resort, to the ignorance in which the

people are still immersed in spite of State education. The Home Office, the sanitary inspector whom it deputed to the seat of infection, the sanitary officer acting at his instance, the practitioners of the province, backed by the municipal authorities—all alike are "suspect" in the eyes of the populace, who, under that suspicion, deny themselves in presence of a loathsome and often fatal disease the benefit of a safeguard recognised as of sovereign efficacy in all civilised nations—even, teste Massaia, in benighted Ethiopia. But the interests at stake are too vital to admit of this defiance of hygienic law, and the approval, at headquarters, of the measures now taken, seconded by Government subsidies and the erection of isolation huts, above all, the preponderating good sense of the better educated, may be trusted to prevail. It would indeed be more than regrettable if, at the opening of the tourist season, the infatuation of the faex populi were allowed to deter the travelling world from one of its favourite winter resorts.

A Medical Martyr.

The sixth meeting of the "Società Italiana di Patologia," held on Sept. 27th, attracted a numerous body of the profession to the Aula Magna of the University of Modena, under the presidency of the Senator Dr. Pio Foa of Turin. In the course of the day a "targa" (memorial shield) with the portrait of Profesor Tito Carboni of Tortona, a pupil of Dr. Foa, was unveiled in the presence of the congressisti. A felicitously worded inscription from the pen of Dr. Mariano Patrizi, professor of physiology in the Modenese School, set forth the many merits of the deceased, who, a brilliant student at Turin, had achieved an honoured name in pathological research when, at the age of 42 years, he succumbed to pyæmia contracted while conducting an experiment in the laboratory. Touching attestations of Carboni's exemplary life and work were delivered by Dr. Arnaldo Maggiora, professor of hygiene at Modena, and by his old master, Professor Foa, after which the congress proceeded to business—the first paper on the agenda being Professor Bonomo's on Tuberculosis.

The Recent National Congress of Midwives.

The Seventh National Congress of Midwives was held at Bologna in September, and in response to an invitation sent through Sir William Sinclair by the president of the Congress, Professor Pazzi, the English Central Midwives Board asked Miss Rosalind Paget to attend as its delegate. Miss Fynes-Clinton represented the Incorporated Midwives' Institute. A most cordial reception was accorded both by the medical faculty and the midwives to the English representatives, who were invited to attend an operation at the "Clinica" by Professor Calderini, the well-known obstetrician. Opportunity was also afforded them of seeing the routine work of the Maternity Hospital. Italian midwives undergo a two years' course of training, and hold a position of considerable importance, and the Congress has no doubt proved an interesting object-lesson to the English visitors in the organisation and control of their profession.

The Congress of Internal Medicine at Milan.

The congress of Internal meatures at muan.

The outstanding features of this meeting were three in number: (1) the Senator Mangiagalli's paper on the "Fattore Meccanico ed il Fattore Biologico nella Patologia della Gravidanza" (The Pathology of Pregnancy: its Mechanical and its Biological Factor); (2) "The Baccelli Treatment of Tetanus"; and (3) the foundation of the National League Against Malaria. The first of these evoked special interest from Dr. Mangiagalli's well-known mastery of the whole field of obstetrics, wherein he has shown himself a worthy successor of Edoardo Porro. But the rigidly scientific tenor of the exposition, while impressing the audience profoundly, was so technical and so detailed that even experts, clinical and consultant, were fain to reserve judgment on it till they could peruse it in published forman opportunity which they will soon enjoy.

The Baccelli Treatment of Tetanus.

This again was a most interesting paper which it will be enough for the present to summarise. Baccelli's experience of the action of phenic acid, hypodermically introduced, in the "neuromyalgia" and the "neuritides" previously found intractable induced him to exhibit it in tetanus. The antitetanic serums of Behring and Kitasato, of Tizzoni and of many others, proved much less efficacious than the treatment by phenic acid, the mortality according to the two former

averaging between 40 and 50 per cent., while Tizzoni's statistics (taken from his last publication) register not less than 30 per cent. The phenic acid treatment, on the other hand, proved much more successful. Indeed, in the latest statistics of Professor Vittorio Ascoli of Rome 25 recent cases subjected to the treatment register but one terminating fatally. Dr. Baccelli then gave a clinical account of an octogenarian (male) treated by him for tetanus in its severest form. Injected in repeated high doses the phenic acid wrought a speedy and permanent cure. Dr. Victor Babes, professor of pathology at Bucharest, has published a series of experiments carried out in his laboratory on dogs, rabbits, and pigeons in which the induced tetanus was successfully treated by the same method, while Kitasato, on the lines of Baccelli, has recently made researches which demonstrate that a phenic acid solution in the proportion of 1.5 per cent. sufficed in half an hour to neutralise the toxic force of the culture in glass of the bacillus of tetanus. Quite lately Baccelli has received from correspondents in clinical schools, non-Italian as well as Italian, confirmation of the efficacy of his method, showing, inter alia, that the phenic acid develops a distinct inhibitory action on the "reflector" power of the tetanic infection on the spinal cord; that it is not only "antithermic" but antitoxic; and that the marvellous tolerance shown by the severest cases under doses of one, two, and even more grammes per diem entitles us to formulate the axiom that "tolerance of an heroic remedy stands in direct proportion to its clinical indication." This axiom, according to Baccelli, holds good for the sublimate he was the first to inject into the veins for infections of various kinds, particularly for those called by Professor Bozzolo of Turin masked infections, corresponding, in part, to the "septicæmiæ crypto-geneticæ" of Leube. The importance of the results claimed by Baccelli for his phenic acid treatment may be estimated from the fact that in the North American Civil War (1861-64) the mortality from tetanus was 93 per cent. and in the Franco-German war 90 per cent.

The National League against Malaria.

The originator of this movement, too long deferred, is Dr. Pietro Castellino, professor of medical pathology in the Neapolitan school, who won his spurs in the campaign against malaria in the Abruzzi, whose knowledge of the malady is in some respects unique, who has conducted at his own expense a "giornale anti-malarioo" already counting three years of life, and who has offered a prize of 3000 fr. (£120) for the best manual for practical and popular use on the prevention and cure of malaria. Professor Castellino, who, I may mention, sits as representative of a provincial constituency in the Chamber of Deputies, has very decided views as to the etiology and prevention of the disease, holding that the true cause of it resides in the soil, which in turn infects the air, which in turn supplies the mosquito with its pabulum. "Bonifica tellurica" must go hand in hand with "bachieve prevention—nature resenting neglected husbandry and neglected hygiene, and penalising the individual and society accordingly. Prophylaxis by systematic exhibition of quinine he does not believe in. Even if the drug could be uniformly, steadily, and intelligently consumed as an adjunct to food the prophylactic result would be nil. This, he maintains, has been proved by statistics, but he allows, on the other hand, that when the disease is present quinine is a certain cure, the vastly extended exhibition of it in regions in which it was previously unknown having reduced the yearly mortality from the disease by more than two-thirds. Admitting that the mosquito is a carrier and propagator of malaria, he quite acknowledges the efficacy of wire gauze as a protection from the insect-a resource which must be put in practice pending the thorough arrest of the infective poison at its source in the "bonifica del suolo" and the "bonifica umana." Quinine, too, must be supplied provisionally in sufficient quantity and in unadulterated quality in the malaria-haunted districts, and to this duty the Government as well as the profession are now thoroughly alive. Inspired by these principles the National League will, he believes, and before the century is much older, solve the enigma of malaria, enjoying, as it will do, the coöperation of the profession with the administration, and of both with the properly instructed individual. The Senator Camillo Golgi, at Wednesday's sitting, read a paper, "Sulla Questione della Malaria," in which he insisted, with Castellino, in the primary necessity of agrarian and hydraulic reform; and

then on the "bonifica umana" as pari passu indispensable, while (again in accord with Castellino) he scouted the "chininizzazione" (quininisation) of the human subject as worse than useless prophylactically and likely to impair the efficacy of the drug when opportunely taken. The "profilassi meccanica" (wire gauze) he recommended as a provisional protection from the mosquito, which he recognised as a carrier merely of the infection. Baccelli followed in the same sense, after which a "statuto" was drawn up and approved, succeeded by the nomination of a "Consiglio Direttivo Centrale" which will guide the operations of the league from its headquarters in Rome.

NEW YORK.

(FROM OUR OWN CORRESPONDENT.)

A Standard Medical Curriculum.

In order further to secure greater uniformity in the courses of medical education in the schools of this country the annual conference of the Council on Medical Education, at its meeting in April, recommended a standard medical curriculum, which has recently been published. In the absence of a standard as a guide there is the likelihood that some colleges would attach too much importance to some subjects and too little to others, or might go to the extreme of overloading the curriculum with unimportant details. The aim and purpose of the council were to arrange a medical curriculum which would not be so overcrowded as to prevent the best training and equipment for practitioners of medicine in all of its branches. In the preparation of the curriculum the council selected a committee of 100 men from the leading medical teachers of the United States and Canada to make an exhaustive examination of the entire problem. The curriculum was constructed on the following lines: (1) The entire medical course was to cover four years of at least 30 weeks each, exclusive of holidays, consisting of at least 30 hours per week of actual work; (2) a four years' high school education, and in addition at least one year of college work devoted to courses in physics, chemistry, biology, and modern languages was to be required for admission; and (3) the total requirement for the study of all branches of the medical curriculum for the four years was to be at least 3600 hours.

Ambulance Preparations at the Hudson-Fulton Celebration.

The Hudson-Fulton Celebration which has just closed was interesting in the elaborate preparation made by the authorities to prevent accidents and to provide facilities for the immediate care and treatment of injuries to persons. A "Committee on Public Health and Convenience" created, with the State Commissioner of Public Health as its chairman. This committee established "medical emergency stations"—viz., field hospitals, of which there were 23, open day and night, and first aid to the injured stations located at intervals of three or four blocks. These hospitals and stations were placed along the entire route of the processions and along the shore of the Hudson river opposite the fleets of battle-ships. The hospitals and stations were fully furnished, equipped, and provided with surgeons and trained nurses by the New York county branch of the Red Cross Society and by the National Volunteer Emergency Service. To supplement the regular city ambulance service a larger number of extra ambulances were provided which were utilised to convey serious cases to the city hospitals. Fast ambulance launches patrolled the river in the vicinity of the warships and accompanied the naval parade. Ambulance stations were located at several piers to facilitate the transfer of patients from the launches to the hospitals. The entire service was conducted without expense to the public. The result of these elaborate preparations was most gratifying. of the several millions of people who participated in this carnival of a week's duration not one suffered a fatal injury.

Course in Public Health.

The University of Pennsylvania has established its proposed course of lectures on public health. It is intended to qualify students for office, and includes courses on sanitary engineering, public water-supplies, theory of hydraulics, sanitary engineering of buildings, inspection of meat, milk, and other animal products, practical methods used in sanitary work, personal hygiene, general hygiene, sanitary legislation,

and the examination of social and vital statistics in the United States. The course of instruction covers a period of one academic year. All those who qualify in the final examinations will receive a diploma and will be designated as "certified sanitarians." Only persons holding the degree of doctor in medicine are eligible to the full course and entitled to the diploma.

Leprosy in the United States.

The official statistics of the Commission of the United States and Marine Hospital Service gave the number of lepers in 1892 as 278, and this is about the present number. Of those of foreign birth the Norwegians were the largest number, being 22; the Chinese are next in the list, 20; Germans and Bohemians are 12 each; and Icelanders are 11. The forms of leprosy are as follows: anæsthetic, 107; tuberculous, 88; and mixed, 83. Of the total number but 72 are segregated. The 41 Icelanders are settled in the State of North Dakota and all contracted the disease in Iceland. The large number of Norwegian lepers may be due to the fact that 170 are reported to have emigrated from Norway to the United States. The presence of so many lepers is attracting public attention, and there is a growing belief that they should be colonised.

Antituberculosis Organisations Among the Negroes.

The mortality among the negro population from tuberculosis has always been excessive. The public interest in the prevention of the disease has awakened an interest in this class, and plans for organising "Coloured Tuberculosis Leagues" have been perfected by the United States Public Health Service. The plan is to organise a branch "league" in every negro church in the country, and any coloured person may become a member of such body by payment of annual dues. The fund from the annual dues is to be used for the care and treatment of society members of that league who may be suffering from tuberculosis, and for dissemination of information by publication and lectures and the establishment of dispensaries and sanatoriums. A State league has been established in Georgia and many branch leagues have been formed.

Ether Day Celebration.

The trustees of the Massachusetts General Hospital have issued invitations to attend the exercises of the Sixty-third Anniversary of "Ether Day," on Oct. 16th. These exercises consist of demonstrations and operations in the hospital in the forenoon and exercises proper in the afternoon, when diplomas will be presented and an address will be delivered by President Eliot of Harvard College.

Sept. 30th.

NOTES FROM INDIA.

(FROM OUR OWN CORRESPONDENTS.)

Plague.

THE plague returns for the week ending Sept. 4th show 1952 deaths, compared with 1811 in the week preceding. The Bombay Presidency reported 703, Madras 155, Bengal 38, United Provinces 455, the Punjab 39, Burma 60, the Central Provinces 243, Mysore State 149, Central India 85, and Rajputana 25.

The Health of Bombay.

The mortality in Bombay during the past week reveals no special features of interest in the health of the city. The total deaths were rather more numerous than in the preceding week, amounting to 602 as against 593, while the number for the corresponding week of last year was 572 and the mean for the past five years 681. Plague has very slightly subsided and accounted for only 27 deaths, the number in the previous week being 31 and in the corresponding week last year 22, while the five-yearly average is 34. Fortunately, cholera also shows signs of abating, the result, no doubt, of the fewer importations which took place. Only two cases came down from Nasik, and the total mortality of the week was 27, as against 43 the previous week. The death-rate is 32.01 per 1000 of the population and the corrected death-rate 31.27. The figure at this time of year previous to the outbreak of plague was 31 .26.

The Manufacture of Quinine.

The report of the Government cinchona plantation and factory in Bengal for the year ending in March last shows

that 938,800 pounds of bark were put through the factory. When the extensions of the factory were completed two or three years ago it was estimated that it would be possible three years ago it was estimated that it would be possessed to manufacture 30,000 pounds of quinine yearly. Last year 36,919 pounds of quinine and 7281 pounds of cinchona febrifuge were manufactured. The output of quinine has practically trebled since 1904. A quite satisfactory start was made with the manufacture of quinine in tablet form, and the factory could turn out any quantity of quinine tablets, but to do so more machinery would be required. The work of building up a reserve of quinine was continued during the year, over 18,000 pounds of quinine sulphate and nearly 4000 pounds of cinchona febrifuge being added to the stock. At the lowest estimate this was worth about one and a half lakhs of rupees, so that though the actual receipts fell short of the expenditure by some Rs. 31,000 the factory had quite a substantial balance to the good in the shape of the quinine reserve. An increase from 4000 to 5000 pounds took place in the amount of quinine utilised for pice packets, and a further large increase under this head is expected during the coming year.

Cholera in Calcutta.

In the annual report of the health officer of Calcutta attention is again directed to the high rate of mortality among Hindus; they form about 65 per cent. of the total population, but contribute 82 per cent. of deaths. suffer particularly from cholera, and there can be no doubt that the careless use of polluted water results in serious loss of life. In spite of the fact that the general water-supply of Calcutta has been improved and increased, the death-rate from cholera has been higher in the past ten years than in the previous decade. Non-Hindus, who use pipe-water freely, suffer comparatively little from the disease; and the conclusion drawn is that the sources of infection are in the river, the canal, and Tolly's Nullah. The Hindus, especially at certain festivals, drink freely from these sources, and hence they are the greatest sufferers. The health officer, in noticing the fact that cholera never leaves Calcutta entirely, observes :-

entirely, observes:—

I do not believe that Calcutta infects itself, so to speak, or that the recurring outbreaks are always indigenous in origin. Numerous deaths occur amongst the thousands who are continually streaming into the city, and many local outbreaks, if not many of the general epidemics, are due to infection brought in. We may, I think, fairly assume that as the disease wanders, so to speak, over Bengal, infecting place after place, the several attacks are due to the import of infected individuals, with the concomitant pollution of water-supplies. The river Hooghly, like the Ganges, probably receives from time to time the germs of this disease, whence they come we know not, and with such infection it produces outbreaks of cholera along its course until it ceases to be dangerous.

The only explanation, therefore, of the continuance of cholera in epidemic form in Calcutta is that the river becomes polluted at irregular intervals. Returns show that after all the great bathing festivals epidemics occur, the Ardhodaya Joge being particularly disastrous. It seems impossible to prevent these outbreaks, for the pilgrims and others who drink the foul water of the Hooghly and Tolly's Nullah, which passes near the Kalighat Temple, cannot be made to understand the risks which they run. Sanitary science is helpless in the face of popular ignorance and superstition; and cholera will take its toll of lives in Calcutta yearly until the people learn to protect themselves against the disease. The health officer deals also with epidemics of small-pox, and his remarks as to the necessity of revaccination are much to the point. It may be noted as an interesting fact, that the whole town of Calcutta is singularly free from malaria, the deaths last year being only 1.2 per 1000. The suburban wards are not so healthy, but even there the mortality is less than 3 per 1000. In rural Bengal malaria is far more deadly, especially in certain districts, which are constantly stricken with fever in the autumn.

The Malaria Conference.

Among officials attending the malaria conference in Simla next month will be Colonel T. E. L. Bate, I.M.S., and Colonel G. F. W. Braide, I.M.S., from the Punjab; Colonel W. G. King, I.M.S., Inspector-General of Civil Hospitals, Burma; and Mr. Cholmeley, Commissioner of the Magwe Division.

The Move of Troops from the Hills.

British troops will this year move down from hill stations at the normal time, unless there is a severe outbreak of malaria in the plains. So far there are no signs of this in the big cantonments. Sept. 12th.

Gbituary.

WILLIAM RIVERS POLLOCK, M.D. CANTAB., F.R.C.P. Lond.,

OBSTETRIC PHYSICIAN TO WESTMINSTER HOSPITAL; SENIOR PHYSICIAN TO QUEEN CHARLOTTE'S HOSPITAL.

By the death of Dr. William Rivers Pollock the medical profession has sustained the loss of a capable teacher and administrator and a devoted follower of our science, while his admirable personal qualities, which had endeared him to a wide circle of colleagues, friends, and pupils, have made that sense of loss far-reaching as well as personal. Dr. William Rivers Pollock was born in 1859, being the third son of Master George Pollock, formerly Queen's Remembrancer, and grandson, therefore, of the famous Chief Baren Pollock, among whose numerous descendants so many have excelled, especially at the bar, in medicine, and in literature, that they have a most interesting tabular statement to themselves in Professor Karl Pearson's "Treasury of Human Inheritance," published by the Francis Galton Laboratory, in illustration of the influences of heredity.

At Haileybury, of which school he was a member from the autumn of 1873 to the spring of 1878, "Jim" Pollock, as his boy friends always called him, showed little promise of future success in the practice of an intellectual profession. Always industrious, he never found learning easy, but he attained considerable distinction in athletics, for which he was well fitted physically and to the mastery of which he brought to bear some of the methodical persistency which characterised his work in after life. At Haileybury, as later, his high moral character and unobtrusive "goodness," his geniality and unaffected charm of manner, won for him the affectionate esteem of all with whom he was brought into contact.

On leaving Haileybury he entered St. George's Hospital, where his father's cousin, Mr. George Pollock, was at the time senior surgeon. He was an industrious student, and more than at school showed the quality of mind which later secured him his high position in medicine. Having qualified as M.R.C.S. Eng., he duly became house surgeon. He was also a prominent football player, and repeated his athletic prowess at Haileybury, in particular becoming known as one of the best hurdle-racers in the country. On the termination of his appointment at St. George's Hospital he was elected house surgeon and anæsthetist to Addenbrooke's Hospital, Cambridge, entering at the same time as an undergraduate at Trinity College, Cambridge. In 1888 he graduated as M.B. and B.C., finding time to complete his medical course while discharging his hospital duties under such vigilant eyes as those of Sir George Paget and Sir George Humphry, who was especially attached to him, and while at the University he confirmed his successes as a hurdler by winning the inter-University contest in 1884 in the then record time of 16 seconds. He did not represent the University in the athletic field in following years because he sustained a server and observe in the sustained as severe and obscure injury leading to extensive and acute phlebitis of the iliac veins which spread to the inferior vena cava and nearly proved fatal. The condition was probably due to the violent muscular exertion of hurdle-racing, and although an early diagnosis, prompt treatment by the medical staff at Addenbrooke's and Mr. George Pollock, and careful nursing restored him to health and vigour, the abdominal and venous trunks were greatly and permanently obstructed, leading to the development of a vast series of superficial veins, and necessitating the wearing of elastic supports over the lower limbs and abdomen.

On leaving Cambridge Pollock took a long sea voyage, in the course of which he met his future wife, who was the daughter of Mr. James Horne Stewart of Bathurst, N.S.W., and completed his restoration to health. He returned to London, and having decided to practise in obstetric medicine took the Membership of the Royal College of Physicians of London in 1890, and was elected in 1891 assistant physician to Queen Charlotte's Hospital. In 1893 he was appointed assistant physician to the Westminster Hospital, and at the time of his sudden death he was senior physician to the Westminster Hospital. In both capacities he rapidly established a position as one of our leading obstetricians. As a teacher he succeeded because not only had he the necessary learning and gifts of arrangement and

exposition, but he had a pronounced vein of dry and quiet humour. A very tall, serious-looking man of a notably undemonstrative manner, a droll story or an apt allusion gained point by his superficial appearance of melancholy and his aptitude as a mimic. By the various students under his teaching Pollock will be greatly missed, and no less so by his colleagues upon the staffs of the two great charities which he served. As treasurer of the medical school of Westminster Hospital he gave up his time without stint to the perfecting of the working arrangements of the school and to regular attendance at committees, and both at Westminster Hospital and at Queen Charlotte's Hospital he was most earnest in his endeavours to improve the clinical teaching in midwifery. All that he did and said on the subject was informed with practical knowledge, for in addi-tion to the appointments which we have mentioned he was consulting obstetric physician to the Westminster Dispensary and had been physician both to the St. George's, Hanoversquare, Dispensary and to the Grosvenor Hospital for Women and Children. He was also examiner in midwifery and diseases of women both at the English Conjoint Board and the University of Cambridge. In 1901 he was elected a Fellow of the Royal College of Physicians of London.

We have said almost enough to show the manner of man that Pollock was, for this brief record indicates the straightforward and simple character of the man and his steady devotion to work, which were the things that combined to bring him professional success and to bring to light that clinical skill which he always appeared to hide; but we add two brief notes from personal friends, one of whom was Pollock's teacher and the other his fellow student, because it is not always that a man is regarded with exactly the same affection and respect by his seniors and his contemporaries.

Mr. J. Warrington Haward writes: "To his numerous friends the death of Rivers Pollock is an irreparable loss. It not only takes from us a physician whose sympathetic insight into character and whose acute perception of symptoms made him an exceptionally valuable consultant, but it also robs the medical profession of one who maintained its highest traditions and who set an example of the most perfect and straightforward uprightness. In private life he was a delightful companion, full of wit and humour, and with a most amusing power of mimicry. He was, moreover, kindly, good-natured, and thoughtful for others to an extent which made him universally beloved. To his intimates his death has brought deeply felt sorrow and regret."

Dr. F. W. Hewitt writes: "Absolutely frank and straightforward in all his dealings with others, Pollock never seemed to find it necessary to adopt that unsympathetic brusqueness which so often characterises the so-called honest man. He was ever considerate for the feelings of others. whether they were rich or poor; ever courteous, ever kind, ever unselfish. Though religious in the best sense of the term, he never paraded his religion. He had a merry wit, a love of the ridiculous, and a keen sense of humour which endeared him to those who knew him best. He rarely, if ever, spoke of himself or of the physical disabilities from which he suffered though his intimate friends were well aware how greatly the latter handicapped him when in active work. By his death the medical profession has lost more, perhaps, than it realises.'

Dr. Hewitt's allusion to the deeply religious character of Rivers Pollock will be appreciated by all who knew him. His tenderness and loveableness, no less than his cheerful sense of humour, had their origin in his happy faith. This it was that enabled him, though suffering from severe physical disability, to carry on, and carry on cheerfully, his busy professional life and to project himself with the fullest sympathy into the lives of his patients.

He has left behind him a widow and two children, a son at Cambridge and a daughter a few years younger. With them we sympathise in their great bereavement.

GEORGE JOSEPH COOPER, M.R.C.S. ENG., L.S.A., M.P.

WE have to record the sudden death of one of the few medical practitioners sitting in the present Parliament, a man who was not only an enthusiastic politician but at the same time a hard-working member of his profession. If George Joseph Cooper, who was born in 1844, was educated at Leeds Grammar School and subsequently at the edical schools of Leeds, Manchester, and University College Hospital. He qualified M.R.C.S. Eng. in 1867 and took his following the debate until 6 or 7, when he returned home-

L.S.A. four years later. He gained his early clinical experience as resident medical officer at the Poplar Hospital for Accidents, and subsequently became house surgeon at the Bristol General Hospital. Returning to London, he settled in practice in Bermondsey, where he has lived ever since. He was not long in entering public life, taking a prominent interest in various questions of social and municipal reform, with the result that he was elected to the London County Council in 1889, serving on the Progressive side for 17 years, during 13 of which he was a member of the public health committee and for six years its chairman. He was on the asylums committee for 13 years and served on 14 other committees, in the business of which he proved himself an indefatigable worker. The scheme which led to the foundation of the Colony for Epileptics at Epsom was the outcome of Mr. Cooper's professional knowledge, and its successful realisation was in great measure due to his administrative ability and powers of persuasion. Perhaps his chief service to the public health was during his chairmanship of the committee charged with its protection, when his personal tour of every common lodging-house in London, and the consequent revelation of the danger from fire and infection to which many of their inmates were exposed was chiefly responsible for the formation of the register of lodging-houses. His special knowledge was also of considerable service to the Council during the small-pox epidemic of 1902, and more recently in dealing with the problem of a pure milk-supply for the metropolis. His municipal services earned him a place on the Commission of the Peace for the County of London. He only severed his connexion with the London County Council when at the last general election he was asked to stand as the Liberal Parliamentary candidate for Bermondsey, where he had become a well-known social reformer and was extremely popular with the working classes, amongst whom his medical practice largely lay. He gained the seat for his party by a very decisive victory, and during the four years that he has since spent at St. Stephen's he has taken a close interest inquestions affecting public health and the medical profession: He was among those who made a successful appeal to the Chancellor of the Exchequer to grant a rebate on the tax on petrol used by medical men in their motor-cars, and was one of the speakers when Mr. Lloyd George received a deputation on the subject. In fact, the second last division in which Mr. Cooper voted took place in connexion with the schedule of the Finance Bill dealing generally with rebates on motor spirit duty.

During the present session of Parliament Mr. Cooper introduced an Ansesthetics Bill. It stood on the order paper for second reading at the time of his death. Owing to the motions for its rejection of which notice had been given there was, of course, no chance that it would be further proceeded with this year, but he did not withdraw the Bill. He promoted an early Bill for the provision of a metropolitan ambulance service, which, however, was dropped pending the investigation of the Departmental Committee on that subject. Mr. Cooper was as enthusiastic in his Parliamentary duties as he had been when a county councillor, and there is little doubt that he allowed too great a strain to be placed on his health by his close attention to his work at Westminster, which he carried on without abandoning a professional practice of an exacting class. Only a man of exceptional grit could have served both his party and his patients as devotedly as did Mr. Cooper. He was in the House of Commons and apparently well on the evening of Oct. 6th, but was seized with sudden symptoms after he had returned home. His condition grew rapidly worse and he died within 24 hours. His remains were buried on Oct. 12th, in the presence of a gathering which included several of his former colleagues of the County Council and of the House of Commons, amongst whom was the President of the Local Government Board.

Mr. Cooper leaves a widow, a married daughter, and four sons, to one of whom, Mr. Reginald Cooper, we are indebted for some of the foregoing facts of his father's career, and the same gentleman has given us the following typical time-table of a recent day's work such as Mr. Cooper was doing. almost down to the time of his death. From 9 A.M. until 11 he would see patients at home and then pay pro-fessional visits until 1.30 or 2 in the afternoon. After a light lunch he was to be found in his place in the House of Commons as early as the Speaker, and he remained keenly

for two hours more work in his surgery. He then returned for an all-night sitting of the House, sometimes addressing a meeting of his constituents on behalf of the Budget on his way back to Westminster. To find a match for such public activity in a medical practitioner we have to cast our minds back to the strenuous life of the Parliamentarian and reformer who founded this journal.

EDWARD CLAPTON, M.D. Lond., F.R.C.P. Lond., F.R.C.S. Eng.

LATE PHYSICIAN TO, AND LECTURER ON MATERIA MEDICA AND THERAPEUTICS AT, ST. THOMAS'S HOSPITAL.

Dr. Edward Clapton, whose death we announced last week, was not known to the present generation of medical men as an active practitioner, for he has lived in retirement at Lee for a considerable time, and was in his eightieth year when he died. He was associated throughout his active career with St. Thomas's Hospital, where he passed his student life and upon the staff of which he served subsequently. He was a man of great industry and capability, and was one of the few who have taken the Fellowship of the Royal College of Surgeons by examination and subsequently turning their attention to medicine have been elected to the corresponding dignity of the senior College. In the year 1857 he graduated M.D. at the University of London and also took his F.R.C.S. Eng., and in the next year he was admitted to the Membership of the Royal College of Physicians. At this time of his life the subject of plants and their medicinal application, in which he always took a lively interest, began to engross his attention, and in 1860 he was appointed lecturer on botany in St. Thomas's Hospital Medical School, a post which was the preliminary to his appointment as assistant physician and lecturer on materia medica in the following year. Ten years later he was elected full physician to the hospital, a post from which he retired in 1875 when he was still in middle age, though he remained in active practice for many years later. He took a great interest in other matters besides those immediately concerned with his profession. A religious man, he was an earnest student of Biblical archeology, as was evidenced by his works on "The Precious Stones of the Bible" and his "Life of St. Luke," a catena of statements collected from the New Testament, Josephus, and the writings of the Fathers. In this little book he made the ingenious suggestion that "the thorn in the flesh, the messenger of Beelzebub," of which St. Paul complained, was recurrent malaria produced by mosquitoes under the control of Beelzebub, the Lord of Flies, a theory which would seem to credit the apostle with an astonishing gift of scientific prevision. He wrote a "Life of St. George," and also turned his attention to the history of his own science. Many will remember how Dr. Clapton journeyed to Cos to identify the plane tree under which the Father of Medicine sat to expound his wisdom, and how his modern disciple was so confident that he had achieved his quest that he presented the Royal College of Physicians of London with two branches plucked from the sacred tree. He wrote freely upon drugs, amongst his papers being those on the "Acid Oxalates of the Earths," the "Action of Copper in the Human System," and the "Action of Tea," whilst he prepared a map of the geographical distribution of the medicinal substances contained in the British Pharmacopæia of 1867. Dr. Clapton had a very practical and enlightened knowledge of the action of medicines and their variability in different constitutions. Besides his professional fellowships he held those of the Linnæan and Zoological Societies, and he was no collector of empty titles but a man who followed up keenly every interest with which he concerned himself. No man, perhaps, followed out more thoroughly the maxim that if a thing be worth doing it should be done with all one's might. The way in which he undertook the examination of the health resorts at home and abroad was an illustration of this. In holiday times he visited in succession all the spas of Europe in order to assure himself of their utility or the reverse, and his authority in this matter was undoubted. We are indebted to one of his former colleagues at St. Thomas's Hospital for the following appreciation of his personal qualities.

"Dr. Edward Clapton was the type of an amiable gentleman. We shall long remember his earnest, modest gaze, at once the expression of his gentle, cheery nature, and the

assurance to friends and patients alike that there was a ready access to a heart full of human sympathy. In action he was an indefatigable worker, and it was not until the yoke of many years oppressed him that his friends induced him to cease from labour. With great reluctance he did so, and gave up most of his cherished work. But even so he turned with avidity to the pursuit of a hobby which had occasionally influenced him—the formation of a collection to illustrate the early history of Judaism, of Christianity, and of Medicine—a collection which I believe to be unique. was very pleasant to listen to him when with uncommon lucidity and enthusiasm he expounded the symbolism of the precious stones in the breast-plate of the high priest. ence to these matters reminds one of the personal interest which he took in the rearrangements of the parochial matters incident to the establishment of the episcopate in Southwark. His friends have often said that he ought to have been a bishop, and truly he would have well filled a cathe-To know him was to esteem him, and to know dral throne. him intimately to love him."

Dr. Clapton's remains were buried at Stamford, Lincs, on Oct. 2nd, on which day a memorial service was held at the church of St. Margaret's, Lee.

DEATHS OF EMINENT FOREIGN MEDICAL MEN.—The deaths of the following eminent foreign medical men are announced:—Dr. Weeks, formerly professor of surgery at the Medical School of Maine, Brunswick.—Dr. W. T. Smith, formerly professor of physiology in Dartmouth Medical School, Hanover, U.S.A.—Dr. Heurtaux, formerly professor of clinical surgery in the Nantes Medical School and associate of the Paris Academy of Medicine.—Dr. Tourneaux, formerly physician to the Rouen hospitals.—Dr. Julius Elischer, privat docent of gynæcology in the University of Budapest.

Medical Rews.

EXAMINING BOARD IN ENGLAND BY THE ROYAL COLLEGES OF PHYSICIANS OF LONDON AND SURGEONS OF ENGLAND.—At the Second Professional Examination of the Examining Board in England in Anatomy and Physiology held on Sept. 30th and Oct. 1st, 4th, and 5th, 70 candidates presented themselves, of whom 54 per cent. were approved and 46 per cent. were rejected. The following are the names of the successful candidates:—

Edward Smith Abraham, University of Bristol; Harry Arnold Ash, Guy's Hospital; Raymond Brewitt-Taylor, St. Bartholomew's Hospital; Nai Cheune, London Hospital; Edward Robert Cecil Cooke, B.A. Cantab., Cambridge University; Frank Cuninghame Cowtan, St. Thomas's Hospital; William Townsend Dobson, University College, Cardiff; Alexander Rentoul Esler, St. Thomas's Hospital; Meredydd Ffoulkes, St. Thomas's Hospital; Ali Athar Hassan Fyzee, Bombay University; Hubert Gibson, Liverpool University; Norman Grellier, Charing Cross Hospital; Cecil Cantilupe Harrison, B.A. Cantab., Cambridge University and St. Mary's Hospital; William George Helsby, Charing Cross Hospital; Cecil Cantilupe Harrison, B.A. Cantab., Cambridge University and St. Mary's Hospital; William George Helsby, Charing Cross Hospital; George Ashby Hooton, St. Bartholomew's Hospital; George James Proctor Huddleston, University College; Frank Mainwaring Hughes, London Hospital; Frederick Malcolm Stirling Hulke, Middlesex Hospital; Arthur Richard Jennings, B.A. Cantab., Cambridge University; James Evelyn Thoresby Jones, University College; Geoffrey William King, Guy's Hospital; Edmund Thomas Howard Lea, King's College and Westminster Hospital; Charles Cooper Ling, London Hospital; Edward MacMahon Mahon, Guy's Hospital; Oswald Pitt, Manchester University; Maitland Radford, University College; Harold Robinson, Manchester University, Arthur Burch Rosher, Charing Cross Hospital; Herbert Sharpe, B.A. Cantab., Cambridge University and Guy's Hospital; Bombay University and St. Bartholomew's Hospital; Arnold Viney, St. Thomas's Hospital; Trevor Mathias Owen Williams, B.A. Cantab., Cambridge University Hospital; Arnold Viney, St. Thomas's Hospital; Trevor Mathias Owen Williams, B.A. Cantab., Cambridge and Birmingham Universities; and Henry Stanley Young, St. Thomas's Hospital:

At the quarterly examination in Practical Pharmacy held on Oct. 7th and 8th the following gentlemen were approved:—

Alan Douglas Anderson, University College; Sealy Highmore Andrews, B.A. Cantab., Cambridge University and St. Bartholomew's Hospital; Cecil Stuart Baxter, Liverpool University; Cecil Bluett, Sydney University and London Hospital; Lancelot Bromley, B.A. Cantab., Cambridge University and Guy's Hospital; Arthur Charles Oakley Brown, Birmingham University and private study; Norman Stuart Carruthers, Guy's Hospital; Thomas Hungerford Cresswell, Middlesex Hospital; David Lloyd Davies, University College, Cardiff; Henry Harvard Davis, Guy's Hospital; James Anthony Delmege, Guy's Hospital; James Douglas Driberg, London Hospital; Bertle Cecil Eskell, University College, Bristol; Arthur George Bisset Fenwick, St. Thomas's Hospital; Frederick Thomas Fisher, Birmingham University; Robert William Beor Gibson, B.A. Cantab., Cambridge University and St. Bartholomew's Hospital; Kenneth Banks Greenwood, London Hospital; Bvan Williams Griffith, University College, Cardiff; Norman Lester Guilford, King's College; Edward Hosward Heston, London Hospital; Herbert Richard Barnes Hull, University College, Cardiff; Sydney Anderson Keys, Middlesex Hospital; Thomas Clatworthy Kidner, private study; Alfred Bertle Kramer, Edinburgh University and London Hospital; William Ewart Latham, Liverpool University; David Charles Lloyd, Guy's Hospital; James Parkinson Lupton, St. Thomas's Hospital; William Fidler Mason, Leeds University; John Mitchell Mehaffey, London Hospital; Claude Harry Mills, Guy's Hospital; Charles Gordon Holland Moore, B.A. Cantab., Cambridge University and St. Bartholomew's Hospital; Richard Goodhart Oram, Guy's Hospital; William Percival Penhalc, Middlesex Hospital; Harold Fey Percival, B.A. Cantab., Cambridge University and Guy's Hospital; Walter Alexander Reynolds, St. Mary's Hospital; Charles Dudley Roberts, Guy's Hospital; Alec Linford Saul, L.D.S. Eng.. Guy's Hospital; Thomas Harold Thomas Stoney Sharpley, Guy's Hospital; Thomas Harold Thomas, London Hospital; Llewellyn Rhys Warburton, St. Thomas's Hospital; Alec Linford Saul, L.D.S. Eng.. Guy's Hospital; Vivian Thomas Pearce Webster, B.A. Cantab., Cambridge University and Guy's Hospital; Thomas Harold Thomas, London Hospital; Llewellyn Rhys Warburton, St. Thomas's Hospital; and Leslie Gordon White, Leeds University.

SOCIETY OF APOTHECARIES OF LONDON.—At examinations held recently the following candidates passed in the subjects indicated :-

PRIMARY EXAMINATION, PART II.

Anatomy.—J. M. Coplans, Westminster and Guy's Hospitals; M. J. McEnery, Royal Free Hospital; O. W. D. Steel, Cambridge and London Hospital; W. G. Tickell, Middlesex Hospital; W. H. Vincent, St. Mary's Hospital; and C. G. Waddington, Leeds.

Physiology.—P. Dvorkovitz, St. Bartholomew's Hospital; J. P. Jones, Guy's Hospital; M. J. McEnery, Royal Free Hospital; O. W. D. Steel, Cambridge and London Hospital; C. G. Waddington, Leeds; and V. J. A. Wilson, Liverpool.

FOREIGN UNIVERSITY INTELLIGENCE. Amsterdam: Dr. J. P. Kleiweg de Zwaan has been recognised as privat-docent of the History of Medicine.—Berlin: Dr. Forster has been recognised as privat-docent of Psychiatry, Dr. J. Katzensteim as privat-docent of Otology, and Dr. Paul Franckel as privat-docent of Forensic Medicine.—Breslau: Dr. Robert Scheller of Königsberg has been recognised as privat-docent of Hygiene.—Budapest: Dr. Edmund Krompecher, privat-docent of Histology and Bacteriology, has been promoted to an Extraordinary Professorship.—Cornell: Dr. Charles N. B. Camac has been appointed Professor of Medicine; Dr. Frank S. Meara, Professor of Medicine and Therapeutics; and Dr. William J. Elser, Professor of Bacteriology.—Greefswald: Dr. Edmund Allard, privat-docent of Medicine, has been granted the title of Professor.—Harrard: Dr. Edward H. Nichols has been appointed Assistant Professor of External Pathology.—Kazan: Dr. V. Burgsdorf has been appointed Professor of Dermatology.—Kharkoff: Dr. A. Cherevkoff has been appointed Professor of Physiology.— Munich: Dr. Max Richter of Vienna has been appointed Professor of Forensic Medicine.—Prague (Bohemian University): Dr. Wenzel Libensky has been recognised as privatdocent of Medicine, and Dr. Franz Procházka as privatdocent of State Medicine. - Vienna: Dr. Karl Reitter has been recognised as privat-docent of Medicine, Dr. Hans Lauber as privat-docent of Ophthalmology, and Dr. Albert Blau as privat-docent of Midwifery.

CHINESE PORK.—A recent report of the City medical officer of health states that the cargo of frozen pigs from China which arrived in the s.s. Palermo on July 31st, after they had been examined by Dr. Herbert Williams, of the Port, for trichinosis, from which they were found to be free, were transferred to the Up-town Stores, in the jurisdiction of the City authority. Although they bore a label stating that they had been inspected and were fit for food, it was found that the glands had not been examined, and therefore such inspection must have been of a perfunctory character and certainly not sufficient to allow of their being admitted without further investigation. For satisfactory examinawhethout that the three signature. For satisfactory channels, the same consider that the same than the debarred from so practising. It was decided that the Board from so practising. It was decided that the Board debarred from so practising. It was decided that the Board consider the suggestion desirable, and that it should be done as the market required. Out of a total consignment of 4663 carcasses 884 have been examined, and of these 80 was considered from the secretary of the Miller General

condemned as diseased and unfit for food. Further information on this subject will be found in our Parliamentary Intelligence in answer to a question put to the President of the Local Government Board.

MEDICAL MAYOR.—Mr. Henry Nuttall, L.R.C.P., L.R.C.S. Edin., L.F.P.S. Glasg., has been selected as the Mayor of Accrington.

THE GRESHAM LECTURES.—Dr. F. M. Sandwith, Gresham lecturer in physic, will give his four lectures for the Michaelmas Term on Oct. 26th and the three following days at the City of London School, Victoria Embankment. He will deal with "Some Medical Aspects of the Poor-law Commission" under the following heads: 1. Historical survey and modern requirements. 2. Medical relief and some causes of pauperism. 3. Pauperism as it affects women and children. 4. Further causes of pauperism. These lectures are open free to the public and will begin each evening at 6 o'clock.

A GENERAL meeting of the Balneological and Climatological Section of the Royal Society of Medicine will be held at 20, Hanover-square, London, W., on Friday, Oct. 29th, at 5.30 P.M., at which the new President, Dr. Leonard Williams, will be inducted to the chair, and will deliver a presidential address entitled "To Redress the Balance." The annual dinner will take place at Oddenino's Imperial Restaurant, Regent-street (Glasshouse-street entrance), on the same evening when Dr. Williams will preside. A testimonial to Dr. S. P. Sunderland for his services to the Balneological Society during the 13 years that he was secretary will be presented at the dinner, and it is particularly hoped that there will be a good attendance.

CENTRAL MIDWIVES BOARD.—A meeting of the Central Midwives Board was held at Caxton House, West-minster, on Oct. 7th, when Dr. F. H. Champneys occupied the chair. A letter from the Clerk to the Privy Council, transmitting an Order of Council continuing the present rules in force for a further period of one year from Sept. 30th, 1909, was received. Before the Board directed this letter to be entered on the minutes Mr. E. Parker Young said that as no provision had been made for the payment of medical men called in by midwives some protest should be made. Resolution after resolution had been sent up by the Board on the subject, but nothing had been done. A short Bill could be passed through Parliament easily because the matter was non-contentious. The Board having had its attention called to the report of the Midwives Act committee decided to hold a special meeting of the Board on Oct. 28th. The chairman, in the course of his remarks, intimated that the question of payment of medical men called in by midwives was one of the important matters that should be considered. A letter from Mr. W. J. Robertson of Clapham, complaining of the conduct of a certified midwife, was further considered. The Board decided to refer the matter to the local supervising authority. A petition, signed by Dr. S. H. Smith of York and other persons interested in the training of midwives in Yorkshire, asking the Board to permit the written examination to be held at some recognised centre in the county, was further considered. The Board decided (a) that Leeds should be constituted one of the provincial examination centres; and (b) that the secretary should be instructed to communicate with the registrar of the University of Leeds as to holding the examinations at the University, and as to the best method of advertising locally for examiners. A letter was considered from the county medical officer of Worcestershire proposing that in cases where a certified midwife sends in a notification of a stillbirth under the Notification of Births Act, the notice required by Rule E. 20 (c) of the Board's rules should not be insisted upon. The Board decided that the reply should be that the Board has no power to dispense with any of its rules. A letter was considered from the clerk of the Hunts county council suggesting that some means—e.g., advertising in the local papers—should be taken to draw the attention of the public and of uncertified women who are still practising as midwives to the fact that after April 1st, 1910, they will be

Hospital for South-East London inquiring what course should be adopted on an occurrence of an outbreak of infectious disease in the house of a parturient woman. The Board decided that the reply should be that the Board does not see its way to advise on such cases as are not dealt with by its rules and regulations.

THE MEDICAL SERVICE OF THE METROPOLITAN ASYLUMS BOARD.—At the last meeting of the Metropolitan Asylums Board the hospitals committee reported that it had considered as to whether or not there should be a time-limit of service for assistant medical officers in the infectious hospitals of the Board. The medical superintendents had been consulted on the subject. The committee had finally decided (1) that there should be a time-limit of service for four years for junior assistant medical officers, and (2) that in the case of junior medical officers promoted to be senior assistant medical officers the limit of the total period of service should be ten years. The decision of the committee was confirmed

by the Board.

Hospital Saturday at Birmingham.—The year's collections to date amount to £19,306 9s. 7d., and contributions are still outstanding. The amount is about £1000 less than last year. The committee again recommends that £10,000 be distributed among the Birmingham hospitals and nursing societies. The convalescent home work has been carried on with great success, and the efforts in obtaining open-air treatment for consumptives have been of great value. The committee feels that the time has come to establish a home for consumptives, and hopes to make an official announcement at an early date. £4000 have been given or promised for this purpose, but at least £8000 more are required.

KING'S COLLEGE (UNIVERSITY OF LONDON).—A course of special lectures on the Pineal and Pituitary Bodies will be delivered in the Physiological Laboratory at King's College on the following Mondays at 4.30 p.m. Nov. 1st, 8th, and 15th, on the Pituitary Body, by Professor W. D. Halliburton, F.R.S; Nov. 29th, Dec. 6th, and Dec. 13th, on the Pineal Body and Reissner's Fibre, by Professor A. Dendy, F.R.S. The course is free to all members of King's College, to all students of medical schools in London, to all internal students of the University of London, and to medical practitioners on presentation of their cards. As a result of the recent examination at the King's College Hospital Medical School (University of London) Mr. P. L. Gibson (Trinity College, Oxford) was awarded the University Scholarship at this school. Proxime accessit, Mr. S. P. Rowlands.

APOTHECARIES' HALL OF IRELAND.—At a meeting of the Court of the Apothecaries' Hall the following were elected examiners for the ensuing year:—Surgery: Professor Conway Dwyer and Sir Thomas Myles. Medicine: Dr. J. M. Day and Dr. John O'Donnell. Midwifery: Dr. R. H. Fleming and Mr. R. J. White. Ophthalmology: Dr. E. Magennis and Dr. R. J. Montgomery. Pathology: Mr. J. L. Keegan and Dr. R. J. Rowlette. Medical Jurisprudence: Dr. J. C. M'Walter and Mr. W. Fottrell. Hygiene: Sir Charles Cameron and Mr. H. F. Powell. Materia Medica: Mr. J. D. Crinion and Mr. Seymour Stritch. Pharmacy: Dr. F. G. Adye-Curran and Dr. E. F. Hanrahan. Physiology and Biology: Professor D. J. Coffey, Dr. W. O'Kelly, and Dr. John Knott. Anatomy: Professor E. P. M'Loughlin and Mr. P. J. Fagan. Chemistry: Professor Hugh Ryan and Mr. B. Bourke Kennedy.

FIRE TESTS WITH FLANNELETTE.—The British Fire Prevention Committee conducted a further series of fire tests with flannelette at their Regent's Park testing station on Oct. 6th, the number of specimens that have now been under review being over 400. The reason for these tests is the great number of fatalities arising from flannelette catching fire. Ordinary flannelette, fine flannelette, non-inflammable flannelette, union and wool materials were under test in lengths of one or two yards and in the form of garments on dummies representing children. The materials had been washed at three different laundries 5, 10, and 20 times respectively. The afternoon's operations went to show that there is certainly a non-inflammable treatment available of

practical value by which fiannelette can be made effectively flame-proof. The object of the tests was to endeavour to obtain precise data as to the fire-resistance of treated flannelette after many washings, as also to devise some easy method of rapidly proving the precise resistance of flannelette sold as "non-inflammable." A report on the subject illustrated by diagrams will be shortly issued by the committee.

THE ROYAL COLLEGE OF PHYSICIANS OF LONDON—Professor J. A. Lindsay will deliver the Bradshaw Lecture at the Royal College of Physicians on Nov. 2nd, taking for his subject "Darwinism and Medicine," and Professor Sir T. Clifford Allbutt will deliver the Fitz-Patrick Lecture on "Greek Medicine in Rome" on Nov. 4th and 9th.

WESTMINSTER HOSPITAL MEDICAL SCHOOL.—
The following entrance scholarships have been recently awarded in this school:—J. S. Ranson: Epsom Scholarship, value 120 guineas. S. B. White: University Scholarship, value 70 guineas. M. C. Breese: Scholarship in Arts, value £60. H. J. Hoyte: Natural Science Scholarship, value £60. A. M. Hughes: Scholarship in Arts, value £40.

UNIVERSITY COLLEGE HOSPITAL MEDICAL SCHOOL.—The annual "public night" will be held on Oct. 20th when Mr. W. Arbuthnot Lane will give an address on "Civilisation." The chair will be taken at 8.30 P.M. by Mr. Arthur E. Barker. The first entrance scholarship at the University College Hospital Medical School (University of London) has been awarded to Mr. G. C. Chubb, D.Sc., and the second scholarship to Mr. Julian Taylor, both of University College, London.

THE NORTH LONDON MEDICAL AND CHIRURGICAL SOCIETY.—The nineteenth session of this society opened successfully on the evening of Oct. 9th with a conversazione, given by the President and council, in the boardroom of the Great Northern Central Hospital. The guests numbered between 60 and 70, and were received by the President, Dr. James Crabb. An excellent programme of music had been arranged by Mr. L. H. Glenton-Kerr, the secretary of the hospital, to whom the society is greatly indebted in many directions. There was a display of surgical instruments and appliances in the hall and the adjoining rooms. A hearty vote of thanks was accorded to the performers and to Mr. Glenton-Kerr and the guests then dispersed after a very successful evening.

LITERARY INTELLIGENCE.—Messrs. Rebman, Limited, announce for issue in October a new work on naval hygiene by Dr. James Duncan Gatewood of the United States Naval Medical School, and a little book by Dr. Robert Park entitled "The Case for Alcohol"; or, the Actions of Alcohol on Body and Soul, based largely upon the researches and discoveries of the late M. Emile Duclaux of the Pasteur Institute in Paris. The same publishers have also in the press a new edition of Sir John William Moore's well-known book on "Meteorology, Practical and Applied," which has been revised and largely rewritten, and the authorised translation into English from the German of Dr. Max Joseph's "Short Handbook of Cosmetics."—Messrs. Skeffington have in the press and will publish immediately a new book by Dr. A. G. Mortimer entitled "The Shadows of the Valley." The book is intended to supply a guide in sickness and death for the use of sick people and for all persons who minister to them.

ANNUAL DINNER OF THE CONTINENTAL ANGLO-AMERICAN MEDICAL SOCIETY.—The annual dinner of this society was held on Oct. 9th in Paris, Sir Malcolm Morris, K C.V.O., being in the chair. Among the guests were Professor Robin, Professor Segond, and Professor Chauffard. The chairman, in his toast to "The Society," laid stress on the fact that the presence of English and American medical practitioners in a health resort brought to it an undeniable increase of prosperity. Moreover, they protect their countrymen from falling into unworthy hands, directing them to "the shrines of scientific truth, among which none in the world are more famous than those in the great city of Paris." Hence the utility of the society in bringing to the notice of physicians in the United Kingdom and in America responsible men to whom they

could with confidence entrast their patients. Professor Robin, in an eloquent speech, referred to the practical value of Anglo-Saxon contributions to medical science. Vaccination with Jenner, ansesthetics with Simpson, antiseptics with Lister were cited as examples. In the course of the evening Dr. L. N. Robinson, the former honorary secretary, was presented with a handsome silver loving-cup as a token of esteem and gratitude for his services to the society, which now entered into its twenty-first year of existence.

Parliamentary Intelligence.

NOTES ON CURRENT TOPICS.

The Holiday of the Commons.

A MUCH-NEEDED holiday of a week has been taken by the House of Commons. The committee stage of the Finance Bill having been concluded, it was necessary that a short interval should elapse before the proceedings on report were begun. The Government, recognising that the strain put on the physical endurance of Members during the past few months has been without parallel in recent years, wisely resolved to give the House a holiday. It was welcome on all sides, especially to the Members of the Opposition, some of whom have expended a great amount of energy in critising the details of the Finance Bill. The air at Westminster has recently been charged with political rumour as to the fate of this measure, and when the House resumes, the strenuous Parliamentary life will begin again with redoubled energy. breathing space of a week is therefore felt to be a great relief.

Medical Men and the Petrol Duty.

The CHANCELLOR of the EXCHEQUER some time ago promised to a deputation of medical men that a rebate of half the duty would be given to members of their profession in respect of the petrol used by them in their motor cars. Mr. LLOYD-GEORGE, accordingly, has moved an amendment to the fifth schedule of the Finance Bill to carry out his romise. It was accepted without discussion and relieves from half the petrol tax "motor spirit used for the purpose of supplying motive power to a motor-car kept by a duly qualified medical practitioner while it is being used by him for the purposes of his profession."

The Housing and Town Planning Bill.

The Housing and Town Planning Bill has been read a third time and passed by the House of Lords. The amendments which have been introduced into the measure since it left the House of Commons have been far-reaching and drastic. It is certain that objection will be taken to them when that House comes to consider them, and unless agreement can be reached the Bill will be dropped. Some words used by the Barl of Onewe in the discussions which arose on the third reading are ominous. He confessed a certain scepticism whether the Bill would ever pass into law. It is apparent from the Earl's remarks that the Government is unwilling to accept the measure in the shape to which the House of Lords has reduced it. The next stage in its progress is the consideration by the Commons of the Lords' amendments.

HOUSE OF COMMONS.

WEDNESDAY, OCT. 6TH.

The Decrease of Hydrophobia.

Sir George Keekwion asked the President of the Local Government Board what were the number of deaths and the death-rates per million from hydrophobia in Great Britain and France, respectively, in each of the last 30 years.—Mr. Burss furnished the following written reply: The number of deaths from hydrophobia and the death-rates per million of population in Great Britain in each of the years from 1878 to 1907 are shown in the appended table. Similar information as regards France is, I am informed, not available:—

Year.		Number of deaths in Great Britain.		hs st	Death- rates per million persons living.	Year.	Year.			er hs at n.	Death- rates per million persons living.

THURSDAY, OCT. 7TH.

Reported Case of Beri-Beri in Ireland.

Reported Case of Bert-Bert in Ireland.

Mr. Gonor O'Kelly asked the Vice-President of the Department of Agriculture (Ireland) whether his attention had been called to the fact that a Norweglan named Obsen, employed at the whaling station on Iniskea Island, in the county of Mayo, was recently admitted to the local hospital in Belmullet, and was certified by the hospital doctor to be suffering from beri-beri; and if so, was he in a position to state the causes that led to the outbreak of this disease?—Mr. Redmond Barry (on behalf of Mr. T. W. Russell) answered: The department has no information on the subject.

Mr. Dillon: Will the honourable and learned gentleman make inquiry into the matter, and also into the general feeling of the people in the district?—Mr. Redmond Barry: I will communicate with the Vice-President of the Department of Agriculture on the subject.

Chinese Pork in the English Market.

Chinese Pork in the English Market.

Mr. Fill asked the President of the Local Government Board how much of the Chinese pork had now been passed and placed upon the market; whether the same was all in a good condition; and when the report of the inspectors would be received.—Mr. Burns replied: I am informed that 1182 carcasses out of the whole consignment of Chinese pork had up to, and including, yesterday been thawed out and examined; 107 carcasses had been condemned and the remaining 1075 carcasses had been condemned and the remaining 1075 carcasses had been consumption. I understand that a report to the corporation by the medical officer of health, in which he refers to the results of the examination of the carcasses, so far as it has at present been carried out, will be issued to-day.

Mr. Dillon: Will the right honourable gentleman take into consideration the desirability of absolutely prohibiting the importation of Chinese pork into this country for human food?—Mr. Burns: No, sir, I cannot give any such undertaking.

sideration the desirability of absolutely promoting one importance. Chinese pork into this country for human food?—Mr. BURNS: No, sir, I cannot give any such undertaking.

Mr. KLERRIDE: May I ask whether the right honourable gentleman has received an assurance through the British Ambassador in China that all these pigs had been fed on cooked rice?—Mr. BURNS: Inquiries were made by the Local Government Board some months ago before this consignment arrived as to the character of the pork and as to the method of feeding the pigs, and we were quite satisfied that it was satisfactory. I can state further, in answer to the honourable Member, that the Meat Trade Journal says of this pork: "Such of it as we have had the opportunity of seeing was excellent pork of its kind, and that it realised the prices quoted, proves it; finally, that it passed the double extra inspection of the Port Sanitary Authority and the cagle-eyed examination of the practical inspectors attached to the Central Meat Market demonstrates that such of it as went into the hands of the retail butcher was sound and wholesome." I have myself gone with my officers into refrigerating stores in the wholesale market and into the retail shops and I also had the pleasure of going down to the New Cut, Lambeth, on Saturday night to see whether the opinion of those better qualified than myself could be confirmed by a layman.

Mr. Durvey. Heat the right honourable gentleman tasted the pork?

Mr. Dillon: Has the right honourable gentleman tasted the pork?

Mr. Dilings: Mas the right honourable genteeman tasted the pork?—Mr. Burns: Yes, I have.

Mr. W. Thorne: May I ask what guarantee there is that these condemned carcasses are not used for human consumption?—Mr. Burns: The Port Sanitary Authority and the riverside local authorities, when they condemn animals as being unfit for human consumption, either have them chemically destroyed or send them to the dust-destructed by behaviord.

tion, either have them chemically described.

Mr. Fell: Has the right honourable gentleman received any advices of any further cargoes or shipments of pork from China either arrived or expected shortly to arrive in England?—Mr. Burns: The answer is

Tests for Colour Blindness.

Mr. HENNIKER HEATON asked the President of the Board of Trade Mr. Henniker Heaton asked the President of the Board of Trade whether he was now in a position to give the results of his inquiries as to the tests for colour blindness used by foreign nations.—Mr. Tennant (who repited on behalf of Mr. Churchill) wrote: The Board of Trade is already in possession of a considerable amount of information with regard to the colour vision tests adopted by the principal maritime countries for their merchant services. With a view, however, to making the return moved for and ordered on July 14th as complete as possible, it requested the Foreign Office to obtain further detailed information in the case of certain important countries. On receipt of that information the return in question will be presented.

Appointments.

Successful applicants for Vacancies. Secretaries of Public Institutions, and others possessing information suitable for this column, are invited to forward to THE LANGET Office, directed to the Sub-Editor, not later than 9 o'clock on the Thursday morning of each week, such information for gratuitous publication.

BOYD, WILLIAM, M.B. Edin., has been appointed Assistant Medical Officer at the Derby Borough Asylum.

CONNOLLY, T. J., M.B., B.S.R.U.I., has been appointed Certifying Surgeon under the Factory and Workshop Act for the Kinvarra District of the county of Galway.

CROWE, H. NEVILLE, M.B., Ch.B., M.R.C.S., L.R.C.P. Lond., has been appointed Assistant Surgeon to the Ophthalmic Hospital, Worcester.

GEDDES, A. CAMPBELL, M.D. Edin., Ch.B., has been appointed to the Chair of Anatomy in the School of Medicine of the Royal College of Surgeons in Ireland.

GLASHAN, HERBERT W., M.B. Aberd., has been appointed Assistant Medical Officer to the Natal Government Asylum, Pietermaritzburg.

HUME, J., M.S., C.M., D.P.H., has been appointed Clinical Assistant to the Chelsea Hospital for Women.

- LAPAGE, C. P., M.D. Vict., M.R.C.P. Lond., has been appointed Lecturer in the Observation of Children and School Hygiene to the Manchester University.
- PRICE, E. W., M.R.C.S., L.R.C.P. Lond., has been appointed Certifying Surgeon under the Factory and Workshop Act for the Narberth District of the county of Pembroke.
- SPRAWSON, F. E., M.R.C.S., L.R.C.P. Lond., L.D.S., has been appointed Medical Superintendent of the National Dental Hospital jointly with Mr. Steadman.
- STEADMAN, F. St. J., M.R.C.S., L.R.C.P.Lond., L.D.S., has been appointed Medical Superintendent of the National Dental Hospital jointly with Mr. Sprawson.
- WATSON, C. GORDON, F.R.C.S. Eng., has been appointed Surgeon to the Royal General Dispensary, E.C.

Pacancies.

- For further information regarding each vacancy reference should be made to the advertisement (see Index).
- AYLESBURY, ROYAL BUCKINGHAMSHIRE HOSPITAL.—House Surgeon, unmarried. Salary £100 per annum, with board, washing, and lodging.
- BLACKBURN AND KAST LANCASHIRE INFIRMARY. Senior House Surgeon, also Junior House Su with board, residence, &c. Junior House Surgeon. Salaries £110 and £80 per annum,
- BOURNEMOUTH, ROYAL NATIONAL SANATORIUM FOR CONSUMPTION AND DISEASES OF THE CHEST.—Resident Medical Officer. Salary £10 per month, with board, residence, and washing.
- BRIGHTON, SUSSEX COUNTY HOSPITAL.—Third House Surgeon, unmarried. Salary £50 per annum, with apartments, board, and laundry.
- BRISTOL ROYAL HOSPITAL FOR SICK CHILDREN AND WOMEN.—Assistant House Surgeon. Salary £50 per annum, with board, rooms, and attendance.
- BRISTOL ROYAL INFIRMARY.—Resident Casualty Officer for six months. Salary at rate of £50 per annum, with board, lodging, months. Sals and washing.
- CARDIFF INFIRMARY (GENERAL HOSPITAL).-House Surgeon. Salary £60, with board and residence.
- CITY OF LONDON HOSPITAL FOR DISEASES OF THE CHEST, Victoria Park, E.—Physician to Out-patients.
- COLCHESTER, RSSEX COUNTY HOSPITAL House Physician, also House Salary in each case £80 per annum, with board, washing, and residence.
- CORE. UNIVERSITY COLLEGE.-Demonstrator in Physiology. Salary £150 per annum.
- EVELINA HOSPITAL FOR SICK CHILDREN, Southwark Bridge-road London, S.E.—House Physician for six months. Salary at rate of £60 per annum, with board, residence, and washing.
- HANLEY EDUCATION COMMITTEE .- School Medical Officer (female). Salary £200 per annum.
- Hospital for Consumption and Diseases of the Chest, Brompton. Resident House Physicians for six months. Salary £25.
- HULL, ROYAL INFIRMARY.—Casualty House Surgeon. Salary at rate of £60 per annum, with board and lodging.
- IPSWICH, EAST SUFFOLK AND IPSWICH HOSPITAL.—House Surgeon. Salary £65 per annum, with board, lodging, and washing.
- King Edward VII. Sanatorium, Midhurst, Sussex.—Junior Assistant Medical Officer. Salary £100 per annum, with board, lodging, and attendance.
- KING'S COLLEGE HOSPITAL MEDICAL SCHOOL (UNIVERSITY OF LONDON) -Sambrooke Medical Registrar.
- LAMBETH WORKHOUSE, Renfrew-road, Lower Kennington-lane, S.E.—Assistant Medical Officer. Salary £150 per annum, with board, apartments, and washing.
- LEAVESDEN ASYLUM, Herts. Second Assistant Medical Officer, married. Salary £180 per annum, with board, lodging, and washing.
- LEEK, STAFFORDSHIRE COUNTY ASYLUM, Cheddleton.—Junior Assistant Medical Officer. Salary £150 per annum, with board, apartments, and washing.
- LIVERPOOL DISPENSARIES.—Assistant Surgeon, unmarried. Salary £100 per annum, with board and apartments.
- LONDON THROAT HOSPITAL, 204, Great Portland-street, W.—Assistant Surgeon and two Assistant Anæsthetists.
- MAIDSTONE, KENT COUNTY ASYLUM. Fourth Assistant Medical Officer, unmarried. Salary £175 per annum, with quarters, attendance, &c.
- MARGATE, ROYAL SEA-BATHING HOSPITAL.—Resident Surgeon. at rate of £80 and £120 per annum, with board and residence.
- MERTHYR TYDFIL WORKHOUSE.—Assistant Medical Officer. Salary £120 per annum, with apartments, rations, laundry, and attend-
- MOUNT VERNON HOSPITAL FOR CONSUMPTION AND DISEASES OF THE CHEST, Hampstead and Northwood, Middlesex.—Senior and Junior Resident Medical Officers. Salary £100 and £50 per annum respectively, with board and residence.
- NEW HOSPITAL FOR WOMEN, Buston-road, N.W.—Two House Surgeons also Clinical Assistant (females).

- NOTTINGHAM GENERAL DISPENSARY.—Assistant Resident Surgeon, unmarried. Salary £160, with apartments, attendance, light, and fuel.
- NOTTINGHAM GENERAL HOSPITAL. Assistant House Physician. & £60 per annum, with board, lodging, and washing. Also House Surgeon. Salary £100 per annum, with board, lodging, and Surgeon. washing.
- Paddington Green Children's Hospital, London, W.—House Physician, also House Surgeon, both for six months. Salary in each case at rate of 50 guineas per annum, with board and residence.
- PARTICK, BURGH OF .- Medical Officer of Health. Salary £250 per annum.
- PRINCE OF WALES'S GENERAL HOSPITAL, Tottenham, N.—House Surgeon, House Physician, Junior House Surgeon, and Junior House Physician. Salaries of two former £75 per annum, and of two latter £40 per annum, with residence, board, and laundry.
- EEN'S HOSPITAL FOR CHILDREN, Hackney-road, Bethnal Green, E.— Assistant Resident Medical Officer. Salary £75 per annum, with board, residence, and washing.
- ROYAL BAR HOSPITAL, Soho, London, W .- Honorary Amistant Anæsthetist.
- ROYAL HOSPITAL FOR DISEASES OF THE CHEST, City-road, London, E.C.—Assistant Physician.
- ROYAL LONDON OPHTHALMIC HOSPITAL, City-road, E.C.—Third House Surgeon. Salary at rate of £50 a year, with board and residence.

 ROYAL WATERLOO HOSPITAL FOR CHILDREN AND WOMEN, Waterloo Bridge-road, S.E.—Junior Resident Medical Officer. Salary at rate of £40 per annum, with board and washing.
- ROYAL WESTMINSTER OPHTHALMIC HOSPITAL, King William-street, Strand, W.C.—Pathologist and Curator. Salary £50 per annum. Also Assistant House Surgeon for six months. Salary £20, with luncheon and tea
- St. MARY'S HOSPITAL, Paddington, W .- Assistant Physician to Outpatients.
- Salford Royal Hospital.—House Surgeon. Salary at rate of £60 per annum, with board and residence.

 Stafford, Staffordshife General Infirmary.—Assistant House
- Surgeon. Salary £82 per annum, with board, residence, and
- STAMFORD HILL AND STOKE NEWINGTON CHARITABLE DISPENSARY, N.—Assistant Medical Officer. Salary £100 per annum, with board and residence.
- STROUD GENERAL HOSPITAL.-House Surgeon. Salary £100 per annum, with board, lodging, and washing.
- TAUNTON AND SOMERSET HOSPITAL, Taunton.—Resident Assistant House Surgeon for six months. Salary at rate of £50 per annum, with board, lodging, and laundry.
- TEIGNMOUTH HOSPITAL, S. Devon.—House Surgeon. Salary £80 per annum, with board, lodging, and washing.

 TUNBRIDGE WELLS GENERAL HOSPITAL.—Junior Resident Officer. Salary £80 per annum.
- UNIVERSITY COLLEGE HOSPITAL MEDICAL SCHOOL.—Assistant in Bacteriology. Salary £60 per annum.
- WAKEFIELD, CLAYTON HOSPITAL.—Senior House Surgeon, unmarried.
 Salary £120 per annum, with board, lodging, and washing.
- WESTMINSTER GENERAL DISPENSARY.—Resident Medical Officer.
 Salary £120 per annum, with rooms, gas, coal, and attendance.
 Wolverhampton and Staffordshire General Hospital.—House
 Surgeon. Salary £30 per annum, with board, lodging, and
- THE Chief Inspector of Factories, Home Office, London, S.W., gives notice of vacancies as Certifying Surgeons under the Factory and Workshop Act at Liansawel, in the county of Carmarthen; and at Barnet, in the county of Hertford,

Births, Marringes, and Deaths.

BIRTHS.

- Hume.—On Oct. 5th, at Lahore, India, the wife of Norman H. Hume, I.M.S., of a son.
- LONGLEY.—On Oct. 11th, at Strathearne, Saltburn, the wife of J. Alan Longley, F.R.C.S.B., of a daughter.
- NEILD.—On Oct. 3rd, at 9, Richmond-hill, Clifton, Bristol, to Dr. and Mrs. Newman Neild, a daughter.
- PEACOCK.—On Oct. 6th, at Steeple Aston, Oxon., the wife of Dr. W. E. Peacock, of a son.

MARRIAGES.

- EVANS—FERGUSSON.—On Oct. 11th, at St. Matthias, Richmond, Surrey. Percy Evans, Major R.A.M.C., to Hilds Annie Drummond, younger daughter of the late James Fergusson, F.R.C.S.E., and Mr. Fergusson.
- SANDERS—ALLEN.—On Oct. 6th, James Herbert Sanders, M.D., J.P., of Hong-Kong, to Mary Beatrice, fourth daughter of W. H. Allen, Esp.
- VAUGHAN—Anderson.—On Oct. 6th, at St. John's, Notting-bill.
 Rdmund Wayne Vaughan, R.A.M.C., to Hilda Margaret Anderson,
 youngest daughter of the late Lieutenant-Colonel P. C. Anderson.
 R.A.
 - N.B.—A fee of 5s. is charged for the Innertion of Notices of Birth. Marriages, and Deaths.

Aotes, Short Comments, and Answers to Correspondents.

CORRECTIVE DRUGS FOR ACETANILIDE AND ANTIPYRIN.

In THE LANCET of August 14th, p. 511, we published a note based upon an American official report dealing with the toxic effects of acetanilide and its allied group of drugs. An interesting sequel to that report has been published recently in the same country by Dr. Worth Hale, who has conducted a series of experiments upon animals to determine to what extent the toxicity of acetanilide and antipyrin is modified by certain other drugs (Bulletin No. 53, Hygienic Laboratory, United States Public Health and Marine Hospital Station, Washington, D.C., September, 1909, pp. 60). He finds that the deleterious effect of acetanilide upon the heart is very imperfectly antagonised by caffeine. So far as the contractile power of the heart is concerned, the antagonism is very weak or even not present at all, and in some cases the two drugs seem to combine to depress the heart to a greater degree than acetanilide does when given alone. The heart rate is not slowed after the administration of this combination, as is the case when acetanilide is given alone, and the decreased heart rate due to acetanilide alone tends to become normal upon the subsequent injection of caffeine. Sodium bicarbonate, on the other hand, appears markedly to lessen the poisonous effects of acetanilide upon the heart in the experiments upon the intact animal. Dr. Hale found that the toxicity of acetanilide is considerably increased by codeine, heroin, and morphine, while salicylic acid and the bromides do not seem to alter its toxicity in any way. These experiments indicate, therefore, that caffeine and the opium alkaloids increase the danger of acetanilide mixtures, while sodium bicarbonate appears to be a fairly good antagonist. Although it is generally recognised that antipyrin is less toxic than acetanilide it has never been so popular as an ingredient of headache powders.

Dr. Hale extended his experiments to antipyrin and found that caffeine is not materially antagonistic to it, but that it prevents the slowing of the heart rate. In experiments made upon the intact animal mixtures of these drugs were invariably more poisonous than antipyrin alone. Sodium bicarbonate however, was somewhat antagonistic to the heart effect of antipyrin, but when given to the intact animal it did not seem to lessen the toxicity of the antipyrin in any degree. Dr. Hale's work on these substances forms a valuable contribution to our knowledge of their action. Most of the so-called "headsche powders" contain acetanilide admixed with caffeine or sodium bicarbonate or both. The caffeine was added under the idea, now shown to be erroneous, that it served to counteract the ill-effects of acetanilide on the heart. The addition of sodium blearbonate was made in order to facilitate the ingestion of acetanilide by increasing its solubility. In point of fact, alkaline salts retard solution of acetanilide, and it is possible that sodium bicarbonate acts beneficially for the reason that it prevents the immediate admission of the whole dose of the drug into the blood

HEALTH AND SANITATION IN SIERRA LEONE

Mr. H. E. Leslie Probyn, C.M.G., the Governor of Sierra Leone, in his annual report to the Colonial Office, recalls the fact that the West Coast obtained the sobriquet of "The White Man's Grave" early in the nineteenth century, and says that as Sierra Leone was then and for many years after the settlement it became, and still is, specially identified with the phrase. He urges that modern statistics prove the words to be now a libel, and pleads that the graveyard metaphor should itself be buried. According to the Blue-Book for 1908 the number of deaths caused by malarial fevers has been greatly reduced, and this is attributed to the increasing importance which is being attached to anti-malarial sanitation. Owing to the good water-supply which Freetown enjoys, diseases of the digestive system also continue to decrease in number. On the other hand, owing to the susceptibility of the Sierra Leonean to chills the rate of deaths resulting from diseases of the respiratory organs continues a high one. The infantile death-rate in the last five years has ranged from 461 to 351 per 1000. This high rate is due to several causes, malaria being one; another is ignorance as to proper feeding, care, and cleanliness of the children in the first few months of their existence, and the unscientific midwifery of the middle and lower classes is also a factor. With a view to arriving at some estimate of the prevalence of ankylostomiasis in Freetown experiments were carried out at the clinical laboratory of the Colonial Hospital. Of 100 specimens of faces examined 54 contained ankylostome ova, but in no instance was there observed any symptom directly attributable to the infection, or any skin eruptions such as have been described as due to ankylostomissis. Mr. Probyn writes enthusiastically about the good effects which have followed the carrying out of the hill-station scheme under the provisions of the loan ordinance of 1903 at a cost of £86,000. He remarks: The hill station is a township designed exclusively for Europeans and built at an altitude of 800 feet near the western end of the half circle of high hills overlooking Freetown and the harbour; the mountain railway gives easy access to the station,

while a pure water-supply, beautiful scenery, and provision for tennis and other games enable the residents to live under pleasant and healthy conditions. The hill station was planned as a fortress against the mosquito and was the first important tangible sign that war was to be waged against malaria. It is not and never was intended to be an experiment in the direction of ascertaining whether complete immunity from malaria can be attained by isolation of Europeans from the native community, as it is obvious that Europeans serving on the West Coast cannot live the absolutely isolated life requisite if the principle of segregation is intended to be strictly carried out in a scientific manner. It is the fact, however, that the health of officers at the hill station has been better than that of officers residing in Freetown or on the Protectorate, and this condition is doubtless in part due to the lessened risk of infection which is the result of the limited compliance with the principle of segregation. The European officials in Freetown and at the hill station are less than 100 in number, and recognising the danger of generalising from a few the medical department has adopted a system by which the relative health in different years and different localities is expressed by the days on which during a year the officials resident at a particular place have been on the sick list. According to this test it is found that the antiquinine period, of which the year 1898 may be taken as a type, is the least healthy, and that the improvement shown 10 years later, notable in all cases, is greatest in the case of residents at the hill station, less marked with the firstgrade officers dwelling in Freetown, and smallest in the case of the artisans, fitters, and drivers employed on the railway, who live at Clines Town in the eastern ward of the city.

Antiquinine Period-type, 1898.

A DISCLAIMER.

To the Editor of THE LANCET.

SIR,—The altogether unwarrantable and offensive use of my name in connexion with a recent advertisement of Page Woodcock's Pills is yet another instance of the unscrupulous manner in which the names of medical men are exploited against their will, and which the profession seems utterly powerless to prevent until legislation steps in to its aid. I need hardly say that the firm in question has received instructions for the immediate withdrawal of the advertisement.

I am, Sir, yours faithfully,

G. NORMAN MEACHEN. Devonshire-street, W., Oct. 13th, 1909.

THE ADMINISTRATION OF SANTONIN.

In a recent number of the Journal de Médecine Interne M. Paul Pélissier makes a useful contribution to practical therapeutics in giving precise directions for the administration of santonin. He shows that this drug may be more toxic towards man than towards ascarides, and cites a case in which a fatal result followed the administration of little more than one-third of a grain to a child, aged six months. He insists that santonin should be given under special conditions and in a suitable vehicle, so that it may attack the parasite without being absorbed by the patient. He recommends as preparatory treatment the administration at bed-time and again in the morning, on an empty stomach, of a draught prepared as follows: Take one clove of garlic, cut small, and a glass of milk, and heat for ten minutes over a slow fire, afterwards straining and sweetening to taste. By cooking the garlic in this way its acrid properties are removed and the resulting draught is rendered agreeable to the palate. These draughts are said to render the parasites more vulnerable by modifying their conditions of life, and to introduce into the stomach an essential oil, which excites the acid secretion and diminishes the capacity of the stomach for the absorption of the anthelmintic. The santonin is then administered in the form of an emulsion, prepared in the following way: Dissolve the santonin in almond oil, 5 grammes, and shake with syrup of gum, 30 grammes, and orange-flower water, 60 cubic centimetres. The dose of sautonin is calculated on the basis of 0.01 gramme for each year of age up to a maximum dose of 0.3 gramme. The draught is given in three portions, at intervals of five minutes, the first being given a few minutes after the morning dose previously referred to. During the forenoon lemonade is freely given, and two hours after the administra-tion of the santonin the patient is purged with calomel. M. Pélissier states that, when dissolved in oil in this manner, santonin passes through the stomach without being altered by the gastric juices and exerts its specific action salely upon the parasites. It is essential that the santonin should be completely dissolved in the almond oil.

A FACE PROTECTOR FOR TRACHEOTOMY.

MUCH care has been devised in the perfection of appliances to ensure surgical patients against septic contamination during operation, but every now and then it is tragically brought home to us that the surgeon himself has remained undefended against risks even more serious. This is notably the case during the performance of trache-otomy for diphtheria, which has on

several occasions resulted in the infection of the surgeon with the ex-pectorated matter and the consequent loss of his evesight or even his life and people suffering from other infective conditions have been known to give their disease to their nurses o_{Γ} medical attendants by spitting in their faces. Medical men in the past have been content to take the risk of such occurrences or to safeguard themselves by wearing a gauze mask, but in certain instances a further protection is undoubtedly desirable, and this has been recently supplied by Messrs. Garrould in the form of a light aluminium mask with a glass window which can easily be removed for sterilisation. The apparatus, which

is known as the zymotic face protector, is affixed to the head by a pad and forehead strap, as if it were a laryngoscope, and it affords an efficient protection to eyes, nose, and mouth. We may add that it would be well for the surgeon not to assume the mask until the patient is anæsthetised, as its appearance would be somewhat formidable to a sensitive child. It can be obtained from Messrs. Garrould's, hospital contractors, 150, Edgware-road, London, W.

COMMUNICATIONS not noticed in our present issue will receive attention in our next.

Medical Diary for the ensuing Beek.

ROYAL SOCIETY OF MEDICINE, 20, Hanover-square, W.

TUESDAY.

Pathological Section (Hon. Secretaries—Leonard S. Dudgeon, C. Bolton, M.D.): at 8.30 p.m.

Presidential Address:

Dr. F. W. Mott, F.R.S.: The Present Position of the Neurone Dectrine in Relation to Neuro-pathology.

Mr. S. G. Shattock: Rhabdo Myoma of Urinary Bladder.
Mr. J. Burton Cleland: A Note on Eosinophile Cells in the Exudate from Tick-bites on a Horse.

DERMATOLOGICAL SECTION (Hon. Secretaries—E. G. Graham Little, H. G. Adamson): at 5 P.M. Dr. J. M. H. MacLeod: "Cystic Rodent Ulcer" treated by Radium.

Dr. H. G. Adamson: (1) Small Follicular Syphilide; (2) Multiple Scars simulating Leucodermia Syphilitica. And other Cases.

SECTION FOR THE STUDY OF DISEASE IN CHILDREN (Hon. Secretaries—E. I. Spriggs, M.D., J. P. Lockhart Mummery, F.R.C.S., J. T. Leon, M.D.): at 4.30 P.M.

Dr. A. Manuel: Two Cases of Anterior Poliomyelitis involving the Four Limbs. Dr. A. P. Beddard: A Case of Macroglossia.

And other case

Specimens:

Dr. F. W. Higgs: Lympho-sarcomatosis. Dr. A. C. D. Firth and Dr. E. I. Spriggs: Pulmonary Stenosis.

Dr. A. Dingwall-Fordyce: Notes on the Pathology of some Liver Conditions in Childhood, with a Report of Three Cases. Dr. J. Walter Carr: Case of Pneumococcal Infection in an Infant simulating Generalised Tuberculosis.

EPIDEMIOLOGICAL SECTION (Hon. Secretaries—W. H. Hamer, G. S. Buchanan): at 8.30 p.m.

Presidential Address :

Dr. James Niven: The Relation of Poverty to Disease.

N.B.—Fellows of the Society are entitled to attend and to speak at all Meetings.

OPHTHALMOLOGICAL SOCIETY OF THE UNITED KINGDOM, 11, Chandos-street, Cavendish-square, W.

THURSDAY.—8 P.M., Card Specimens by Mr. B. Harman, Mr. R. Batten, Mr. B. James, Mr. J. H. Fisher, &c. 8.30 P.M., The President (Dr. G. A. Berry): Introductory Address. Mr. P. Smith: (1) A Note on the Making of Pedigree Charts; (2) A Pedigree of Congenital Discoid Cataract.

LECTURES, ADDRESSES, DEMONSTRATIONS, &c.

ROYAL COLLEGE OF SURGEONS OF ENGLAND, Lincoln's Inn Fields, W.C.

Monday.-5 P.M., Prof. S. G. Shattock: Osteoma. Demonstration.)

FRIDAY.—5 P.M., Prof. A. Keith: Specimens illustrating Various Forms of Congenital and Acquired Diverticula of the Ali-mentary Canal. (Museum Demonstration.)

MEDICAL GRADUATES' COLLEGE AND POLYCLINIC, 2,

IBDICAL GRADUATES' COLLEGE AND POLYCLINIC, 2,
 Chenies-street, W.C.
 Monday.—4 P.M., Dr. J. H. Sequeira: Clinique (Skin). 5.15 P.M.,
 Lecture:—Dr. J. Collier: Functional Paralysis.
 TUESDAY.—4 P.M., Dr. H. Campbell: Clinique (Medical).
 Lecture:—Dr. T. Eden: Malignant Ovarian Tumours.
 WEDNESDAY.—4 P.M., Mr. J. Cantlie: Clinique (Surgical). 5.15 P.M.,
 Lecture:—Dr. W. H. B. Stoddart: The Prognosis of Functional Nervous Disorders.
 THURSDAY.—4 P.M., Sir Jonathan Hutchinson: Clinique (Surgical). 5.15 P.M.,
 Lecture:—Dr. G. Carpenter: Heart Disease in Children.

5.15 P.M. Children.

FRIDAY.-4 P.M., Mr. S. Spicer: Clinique (Ear, Nose, and Throat).

POST-GRADUATE COLLEGE, West London Hospital, Hammersmith-

Monday.—10 a.m., Lecture:—Surgical Registrar: Demonstration of Cases in Wards. 2 p.M., Medical and Surgical Clinics. X Rays.
Mr. Dunn: Diseases of the Eyes. 2.30 p.M., Operations. 5 p.M.,
Lecture:—Mr. Pardoe: Undue Mobility of the Kidneys and its

Lecture:—Mr. Pardoe: Undue Mobility of the Kidneys and its Consequences.

TUFSDAY.—10 A.M., Dr. Moullin: Gynæcological Operations. 12.15 P.M., Lecture:—Dr. Pritchard: Practical Medicine. 2 P.M., Medical and Surgical Clinics. X Rays. Dr. Davis: Diseases of the Throat, Nose, and Ear. 2.30 P.M., Operations. Dr. Abraham: Diseases of the Skin. 5 P.M., Lecture:—Dr. Saunders: Clinical Examination of Severe Cases of Gastric Disorder (continued)—Examination of Gastric Contents.

WEDNESDAY.—10 A.M., Dr. Saunders: Diseases of Children. Dr. Davis: Diseases of the Throat, Nose, and Ear. 12.15 P.M., Lecture:—Dr. G. Stewart: Practical Medicine. 2 P.M., Medical and Surgical Clinics. X Rays. Mr. B. Harman: Diseases of the Kyes. 2.30 P.M., Operations. Dr. D. Robinson: Diseases of Women. 5 P.M., Lecture:—Dr. Beddard: Medicine.

THURDAY.—10 A.M., Lecture:—Surgical Registrar: Demonstration of Cases in Wards. 12 noon. Pathological Demonstration:—Dr. Bernstein. 2 P.M., Medical and Surgical Clinics. X Rays. Mr. Dunn: Diseases of the Eyes. 2.30 P.M., Operations. 5 P.M., Lecture:—Dr. G. Stewart: Injuries to Nerves.

EDITORIAL NOTICES.

IT is most important that communications relating to the Editorial business of THE LANCET should be addressed seclusively "To THE EDITOR," and not in any case to any gentieman who may be supposed to be connected with the Editorial staff. It is urgently necessary that attention should be given to this notice.

It is especially requested that early intelligence of local events having a medical interest, or which it is desirable to bring under the notice of the profession, may be sent direct to

Lettures, original articles, and reports should be written on one side of the paper only, AND WHEN ACCOMPANIED BY BLOCKS IT IS REQUESTED THAT THE NAME OF THE AUTHOR, AND IF POSSIBLE OF THE ARTICLE, SHOULD BE WEITTEN ON THE BLOOKS TO FACILITATE IDENTI-SECATION.

Letters, whether intended for insertion or for private informa tion, must be authenticated by the names and addresses of their writers—not necessarily for publication.

We cannot prescribe or recommend practitioners.

Local papers containing reports or news paragraphs should be marked and addressed " To the Sub-Editor."

Letters relating to the publication, sale and advertising departments of THE LANGET should be addressed "To the Manager."

We cannot undertake to return MSS. not used.

MANAGER'S NOTICES. TO SUBSCRIBERS.

WILL Subscribers please note that only those subscriptions which are sent direct to the Proprietors of THE LANCET at their Offices, 423, Strand, London, W.C., are dealt with by them? Subscriptions paid to London or to local newsagents (with none of whom have the Proprietors any connexion whatever) do not reach THE LANCET Offices, and consequently inquiries concerning missing copies, &c., should be sent to the Agent to whom the subscription is paid, and not to THE LANCET Offices.

Subscribers, by sending their subscriptions direct to THE LANCET Offices, will insure regularity in the despatch of their Journals and an earlier delivery than the majority

of Agents are able to effect.

THE COLONIAL AND FOREIGN EDITION (printed on thin paper) is published in time to catch the weekly Friday mails to all parts of the world.

The rates of subscriptions, post free, either from The Lancer Offices or from Agents, are:—

FOR THE UNITED KINGDOM.
One Year £1 12 6
Six Months 0 16 3
Three Months 0 8 2
Three Months 0 8 8

Subscriptions (which may commence at any time) are payable in advance. Cheques and Post Office Orders (crossed "London County and Westminster Bank, Covent Garden Branch") should be made payable to the Manager, Mr. CHARLES GOOD, THE LANCET Offices, 423, Strand, London, W.C.

TO COLONIAL AND FOREIGN SUBSCRIBERS.

SUBSCRIBERS ABROAD ARE PARTICULARLY REQUESTED TO NOTE THE RATES OF SUBSCRIPTIONS GIVEN ABOVE. It has come to the knowledge of the Manager that in some cases higher rates are being charged, on the plea that the heavy weight of THE LANCET necessitates additional postage above the ordinary rate allowed for in the terms of subscriptions. Any demand for increased rates, on this or on any other ground, should be resisted. The Proprietors of THE LANCET have for many years paid, and continue to pay, the whole of the heavy cost of postage on overweight foreign issues; and Agents are authorised to collect, and generally do so collect, from the Proprietors the cost of such extra postage.

The Manager will be pleased to forward copies direct from the Offices to places abroad at the above rates, whatever be the weight of any of the copies so supplied. Address-THE MANAGER, THE LANGET OFFICES, 423, STRAND, LONDON, ENGLAND.

SOLE AGENTS FOR AMERICA-Messrs. WILLIAM WOOD AND Co., 51, Fifth Avenue, New York, U.S.A.

An Address

RECENT ADVANCES IN OUR KNOWLEDGE OF SLEEPING SICKNESS.

Delivered before the Society of Tropical Medicine und Hygiene on Oct. 15th, 1909,

BY ARTHUR G. BAGSHAWE, M.B., B.C., D.P.H. CANTAB.,

DIRECTOR OF THE SLEEPING SICENESS BUREAU, ROYAL SOCIETY.

GENTLEMEN,-In the address I have the honour of delivering to-night I have taken as recent work that which has been published in the last 12 months. The advances which I have endeavoured to chronicle are such as have an immediate bearing on the prevention or cure of sleeping sickness. Sleeping suckness I have considered as meaning infection in all its stages by Trypanosoma gambiense. I have gone beyond my text in suggesting openings for investigation, for it is obvious that such an address as this is of value, if at all, in so far as it indicates not only the ground which has been won, but also the points at which assaults promise

The course of human trypanosomiasis has been commonly divided into stages according to the symptoms. A convenient classification is that of the members of the French Sleeping Sickness Commission, G. Martin, Lebœuf, and Roubaud, who have lately published in a large volume the results of two years' work in French Congo. They distinguished oas en bon état, persons who have no symptoms whatever of trypanosome infection; cas suspects, persons who have symptoms which lead to further investigation; and vas cliniques, cases which can be diagnosed from symptoms alone. A more accurate division which they make when it is possible depends on the result of spinal puncture. If evidence of invasion of the subarachnoid space by trypanosomes is thus obtained the patient is at the second or third stage; if not, he is at the first. By this means some of the patients with no symptoms are shown to be actually at the second stage. In the course of this address when I speak of patients in the first stage I mean those whose cerebro-spinal fluid is normal, or believed to be normal.

TRANSMISSION.

Glossina palpalis.—Since the year 1903 we have known that Glossina palpatis is the transmitter of human trypanosomiasis, but it is only recently that we have acquired accurate knowledge of the conditions of transmission. As is generally known, Kleine, in his paper published in March of this year, showed that after the fly ingests the trypanosome (in this case brucei) an interval of 18 or 20 days occurs, during which it is non-infective, but that after that period it is able to infect susceptible animals. His observations were soon confirmed by Bruce for T. gambiense, and there is every probability that some flies remain infective for the rest of their lives. Infection by interrupted feeding or with an interval of a few minutes is, of course possible, but it seems to me that it must be an unusual occurrence, for trypanosomes are as a rule rare in the circulation, and the quantity of blood contained in the proboscis-tube is so minute that the chance of any trypanosomes being contained therein is small. Bruce, however, still believes that the

mechanical method is by far the commoner.

Kleine has published figures of what must be regarded as T. gambiense in the alimentary tract of flies reared from the pupa, fed at first on animals infected with that trypanosome and afterwards on healthy animals. The forms show a marked differentiation. He has found parasites in the salivary glands as well, but regards their presence there as accidental rather than as bringing tsetse into line with anopheles. He has obtained no evidence of hereditary or

germinal infection.

Sir David Bruce and his colleagues have made a very interesting observation: they introduced under the skin of a monkey a tiny drop of fluid from the gut of a fly fed 75 days previously on an animal infected with T. gambiense there was a palpalis area at hand or within a few miles, and No. 4495.

and afterwards on healthy animals. The fluid was swarming with trypanosomes. Eight days later the monkey became infected. We know, therefore, that the trypanosomes ingested by the fly undergo some kind of development, but whether a sexual process occurs or there is merely such a multiplication as is seen in cultures, we are at present ignorant. If it is found that the trypanosomes are not able at all stages to infect the fly as Todd suggests, the hypothesis that a sexual stage occurs would receive indirect

support.

Kleine found that of 410 flies which had fed on animals infected with T. gambiense 22 became infected, that is, 5 per cent. Since, however, about half of his flies died early in captivity he thought the percentage might be doubled. Whether 10 represents the highest percentage that one would find in nature is, of course, uncertain. Stuhlmann, whose work was done with Trypanosoma brucci and Glossina fusca, infected about the same percentage. Kleine's flies had drawn their infection from monkeys, which were possibly at different stages of the disease and perhaps not equally infective. Experiments to ascertain if Gelssina morsitans or other species of Glossina is able to convey T. gambiense after a similar interval will doubtless be undertaken. Should, however, these be successful there is no reason to anticipate an extension of the disease to palpalis-free regions. All the observations made hitherto support the thesis that sleeping sickness does not become endemic except in palpalis areas.

There are two other possible means of communicating the disease which have supporters—sexual coitus and blood-

sucking insects other than tsetse-flies.

Sexual coitus.—The former hypothesis was brought forward by Koch and Kudicke to explain the occurrence of the disease in women who lived in a palpalis-free area and said that they had never left it. Lately, Kudicke has stated that he has had 44 of such female patients under treatment. Hodges, in an unpublished Memorandum, suggested an explanation of such cases. He wrote: "When the epidemic first swept through the lake-shore district the men, whose employments naturally carried them into the greatest danger, usually suffered first. As the men weakened, their occupations, such as canoeing, were in part taken up by the women, who then ran greater risks and more often contracted the disease, while many of their husbands by this time had either died from it or showed obvious symptoms of its presence." Kudicke, by introducing blood from an infected monkey into the vagina of an uninfected monkey, with careful precautions to avoid injury, brought about an infection. This observation, if confirmed, would suggest the possibility, in the case of a wound or ruptured blood-vessel of the penis, of such an occurrence in man. Here may be cited an observation of Manteufel. He found that if he put blood containing trypanosomes on a patch of unshaven sound skin the size of a florin, allowed the blood to dry and covered the patch with collodion, in the greater number of animals infection followed. He suggested as a reason why trypanosomes do not usually pass through the skin or mucous membrane the presence of some antibody. There are no records in favour of Koch's hypothesis from other parts of Africa.

Mosquitoes, &c.—The members of the Sleeping Sickness Commission in French Congo bring forward evidence in favour of the transmission of sleeping sickness by insects other than Glossina, especially mosquitoes of the genera Mansonia and Stegomyia. This view, expressed in March of last year, is repeated and emphasised in their complete report. They regard *G. palpalis* as the principal agent of infection, but think that mosquitoes, and probably other biting insects, are "important auxiliaries," conveying infection in each hut from person to person during the night. They say that in regions where the natives nurse their sick in their own houses the disease spreads with much greater rapidity than in those where they drive them away. They give instances of one member of a family after another becoming infected, and quote cases in which a native was saved from infection, in their belief, by the use of a mosquito net. They found sleeping sickness extremely prevalent in marshy districts where Mansonia abounded, and attribute to this method of infection in some instances the annihilation of whole villages.

Examination of the data shows that in nearly all the cases

in some instances where the disease spread with great rapidity it is stated that it was of recent introduction and that the natives were badly nourished, either of which would be efficient cause of a severe epidemic such as lately raged in Busoga. It is easy to understand why the disease spreads more rapidly when the sick man remains in the village, for if he is driven away he is no longer preyed on by palpalis, or at least not by the same flies which bite his fellow villagers, and moreover his early death removes the source of infection altogether.

Granted the occurrence of this method of transmission, it is quite impossible to form any conclusion as to its relative importance if the epidemics studied are close to palpalis areas. Under these circumstances any such attempt is mere conjecture. Attention should be concentrated on sporadic cases, patients living out of reach of any species of tsetse, and watch must be kept for signs of the disease in inmates of the same hut. I cannot but think that the French observers ascribe to these "auxiliaries" a more important part than they really play. When we consider that imported cases of sleeping sickness never caused epidemics in the New World; that the disease, wherever it is, endemic or epidemic, hugs the shores of palpatis-haunted lakes and rivers; that in Uganda, inland from the Victoria Nyanza, out of reach of tsetse flies, no instance of infection from a sporadic case has come to light, we must, I think, demand more strict evidence than the French have given us. There are, however, a few cases recorded where the intervention of palpalis, or indeed of any species of Glossina, may, for one reason or another, be excluded, and one must admit that in these rare instances the intermediary was some other insect. 1

I shall not refer here to the experiments on transmission of *T. brucci* carried out by various investigators with mosquitoes and *Stomoxys*. They have, of course, proved the possibility of such an occurrence.

DIAGNOSIS.

The diagnosis cannot, of course, be considered as established unless the trypanosome is found in one or other of the body fluids. As to the course which is best adapted for its discovery there has been some difference of opinion. The members of the French Commission have recently published statistics based on examination of 459 infected persons, and since these examinations have evidently been conducted with much care and the number of cases is large the figures deserve careful study. One of their tables is appended:—

Table from "La Maladie du Sommeil au Congo Français."
(Martin, Lebouf, Roubaud. Paris. 1909.)

_	Examen direct du sang.	Centrifuga- tion du sang.	Sang total.	* Diagnostic ganglion- naire complét.	Ponction lomb- aire.
Nombre d'exa- mens.	417	100	_	400	167
Resultats positifs.	152	92	-	3 53	120
Pourcentages.	36.45	92	96-82	88:25	71.85

^{*} By this expression the authors mean that a gland of each group (cervical, axillary, inguinal, &c.) was, if necessary, punctured.

Blood.—The high percentage of success obtained by direct examination of the blood will be at once noted. The films were wet; 7/8 inch cover-slips were used, a mechanical stage, and a magnification of 276 diameters. Ten minutes were allowed for the scrutiny, and a second slide was, as a rule, not examined. The direct blood method was that by which trypanosomes were found in 9 out of 12 Europeans in the Congo who were recognised to be infected. It is worth noting that in some cases where in a film of blood from one hand no trypanosomes were found, in a film from the other they were detected. By centrifugation of blood in 12 cases at the first stage trypanosomes were found in every one.

Glands.—The glands of 400 infected persons were examined in turn. The parasites were found most often in the cervical glands, 73 per cent.; next in the submaxillary, 69 per

cent.; and in the axillary, epitrochlear, and inguinal, about 50 per cent. To determine the relative frequency with which trypanosomes were contained in the different groups a gland of each was punctured in 78 patients; the cervical group headed the list, but was run very close by the inguinal-71 per cent. and 66 per cent. Seeing that in 11 per cent. of infected persons trypanosomes could not be found in the glands, the percentage of puncturable glands in the patients was studied; in the case of inguinal it was 89, in that of the cervical and submaxillary 87. The authors write: "In our 459 cases of infection we have been unable to do gland puncture 59 times—i.e., in 12 · 8 per cent. either because the glands were too small or because they did not exist." This statement is of great importance. means, of course, that if one relies on gland puncture alone for a diagnosis of human trypanosomiasis at least 12 cases in 100 will be missed because puncture cannot be done. Some of these 12 will have other signs of the disease; others will not. The figures of which the tables are made up are taken from patients examined under the best conditions by all known methods. Let us take another set of figures. Lebœuf, who travelled through part of French Congo studying the disease, made use of gland puncture and direct blood examination only. He examined 552 persons, and trypanosomes were found in the glands of 80. Each group of glands was examined, and 264 punctures were made. In 11 cases in which the glands were punctureable, but he was unable to find trypanosomes in them, they were found in the blood, i.e., in 12 per cent. of the persons recognised as infected. Of these 11, 6 belonged to the bon état class—i.e., they were in apparent health. It appears, then, that if gland puncture alone is employed, even though it is carried out with the greatest completeness and care, 12 out of 100 patients will be passed over, and that, even if clinical signs are watched for as well, between 6 and 7 per cent. will escape detection; and this when the examination is made by an expert. I have gone into this part of the subject at some length because there seems to be a general impression that gland enlargement and gland puncture are by themselves an efficient sign and means of diagnosis of sleeping sickness; clearly, it is not the case. Examination of the blood must never be neglected, and it is especially important, for by its aid only can be discovered the very early, and therefore curable, cases. Those whose business it is to weed out the infected natives in a community should study these figures.

Cerebro-spinal fluid.—The results obtained by the French Commission with lumbar puncture in supposed early cases are remarkable; they examined the cerebro-spinal fluid of 19 persons in apparent health with no symptoms whatever, and in five instances they found trypanosomes. They add that no case in which a trace of blood was found in the fluid is included in their statistics. This shows that until one has examined the cerebro-spinal fluid it is impossible to be sure that a patient is at the first stage.

Broden and Rothain have made a special study of the cerebro-spinal fluid in trypanosomiasis; they regard the presence or absence of trypanosomes as of quite secondary importance, and for this reason collect only 5 cubic centimetres of the fluid. They count the white cells and study their character. A mere increase of small lymphocytes (5 per cubic millimetre being taken as normal) is found in early cases, and Broden and Rodhain think that this increase can be detected before it is possible to find trypanosomes. In later cases there are found also muriform cells and, later still, myelocytes. A histological study is much needed of the central nervous symptoms of persons who have died at an early period of their infection. It may be that changes in the membranes would be detected in quite early cases.

Auto-agglutination of the red blood corpuscles.—Here again Lebœuf, of the French Commission, has added to our knowledge. Among his 552 cases, in 91 of whom trypanosomes were found in the blood or glands, while all of these showed the phenomenon in a marked degree, in 48 others it was present also. Some were almost certainly infected, as could be judged from the symptoms; if lumbar puncture had been done and the blood centrifuged doubtless trypanosomes would have been found in them. Were all the 48 infected? Lebeuf does not commit himself to an opinion. It seems doubtful, however, whether well-marked auto-agglutination ever occurs in African natives apart from an infection by T. gambiense. It is said, however, to occur in certain forms

¹ The cases recorded by the French Commission should be studied in the fine work which they have lately published.

of icterus due to hæmolysis (L. Martin and Darré). More attention should be paid to the subject, for auto-agglutination can be detected before recourse is had to the microscope, and, were it shown to be trustworthy, would be a simple and therefore valuable means of diagnosis. In any case we have in auto-agglutination an added reason for the examination of fresh blood films.

Test animals.—Till recently the test animals used for sleeping sickness were not very reliable. Thiroux and D'Anfreville have found that a species of Cerooptheous (C. ruber or patas), widely spread in tropical Africa, is very susceptible to infection by T. gambiense. Monkeys inoculated from patients showed infection in from 11 to 18 days. They point out that in the case of inoculation of a monkey, one can use many times the volume of fluid which could be submitted to centrifugation, an obvious advantage. This method has its uses, but, in my opinion, for the original diagnosis should be rarely necessary. Culture on artificial media and complement fixation are diagnostic methods of the future.

Gland palpation.—When one is confronted with the task of estimating the percentage of infection in a community and of weeding out the trypanosome carriers, it is clearly impossible to employ microscopical methods in every case, and it is usual to rely on gland palpation for the separation of the natives who are to be examined more fully. It is admitted that this is not a perfect method. The difficulty is not only that infected persons at an early stage are without enlarged glands, but also that there are other conditions which cause adenitis, and though the glands due to trypano-somiasis have a peculiar character which can be recognised by a skilled observer when it is typically present, this character may be masked. The French Commission found that whereas under treatment some glands diminished in size, others did not, and they concluded that the enlargement of these, though they often contained trypanosomes, was due to other causes. There are, moreover, reasons for believing that in some cases the swelling of the glands is never great. We have no data which would indicate to us the interval between the first appearance of trypanosomes in the blood and the time when the glands become large enough to puncture; it probably varies. Heckenroth mentions the case of a boy who had slight suborbital cedema, and in whose blood trypanosomes were found. Not till a year later did any glands become puncturable. The diminution in volume that occurs at a puncturable. later stage, whether the result of treatment or not, is well known and must always be borne in mind. The fact that a single injection of an organic arsenical, such as atoxyl, may cause such a retrogression of glands that they cease in a few weeks to be puncturable, must always be present to workers in Africa, for there are now many such persons abroad. As a means of separation of possibly infected from probably uninfected natives, gland palpation will always be of use; but I doubt the value of statistics of gland enlargement when such a factor as the frequency of other conditions causing adenitis is unknown. If some observer, whose lot it is to examine a large number of natives with a view to check the movements of the infected, were to palpate the glands and examine a blood-film (macroscopically) in every instance, controlling the results by the various microscopical methods, and were to publish his figures, he would materially advance our knowledge. Recent work confirms the observations of Dutton and Todd that the larger the glands the more likely are trypanosomes to be found in them.

Heckenroth, who examined many cases of trypanosomiasis in French Congo, considers ædema at least as valuable an early sign as gland enlargement.

The French observers bring out another point of interest. Lebœuf on seven occasions found a Miorofilaria perstans in a punctured gland. Three of these glands contained trypanosomes also; in the other four patients there was marked glandular enlargement of the cervical group in three cases. No trace of blood accompanied the embryos. It is possible then that the presence of these blood worms may account for some cases of pronounced gland enlargement.

SYMPTOMS.

An excellent clinical study of the disease is published in the French report. Naturally the recent advances in this part of the subject are not numerous.

The French observers have published papers on the nervous manifestations of sleeping sickness—acute meningitis occurring in the second, rarely in the first, stage of the disease, this was a case treated at the first stage. And Nattan-Larrier

perhaps before a diagnosis has been made, and the socalled cerebral and medullary forms. The cerebral forms they classify as diffused and circumscribed. The former are manifested by mental and meningeal symptoms, subacute in character. There is loss of the intellectual faculties. In the circumscribed forms there is irritation of the cortex leading to convulsions or paralysis. Both forms are incurable. The medullary or spinal forms are characterised by paraplegia, with some loss of sensation and bladder troubles. These symptoms progress slowly and respond well to treatment. Hodges, in a report about to be published, remarks on the increase of cerebral symptoms in Uganda. "Paralysis, paresis, and epileptiform convulsions," he writes, "which among untreated cases occurred in a small percentage, are now commonly met with, and are often the precursors of sudden death, which itself was very exceptional before the use of organic arsenic. Sudden or rapid death, in fact, generally preceded by cerebral symptoms, would appear now to be almost the rule among such cases as have received full courses of organic arsenic, while the prolonged lethargic stage which almost invariably marked the end of untreated cases is either scarcely noticeable or absent." I am unable to suggest any reason for I am unable to suggest any reason for

Such symptoms as deep hyperesthesia (Kérandel's sign) and iritis or cyclitis do not come within my period.

TREATMENT.

Many papers on this branch of my subject have been published in the last 12 months. The number of new drugs employed has not been large; it includes arsacetin (the acetyl derivative of arsanilic acid), arsenophenylglycin, and p. aminophenylstibinic acid, which corresponds to arsanilic acid, with antimony substituted for arsenic in the molecule-Experience has been gained in the use of the older drags, such as atoxyl or soamin, with or without mercury, orpiment, tartar emetic, &c.

Arsanilate (atomyl or soamin).—It is certain that these substances are best administered by hypodermic injection. Broden and Rodhain, who gave atomyl by the mouth to 79 patients, concluded that the method was suited only for persons with a normal cerebro-spinal fluid, and that in any case if improvement was not rapid injections should be given. From the evidence we have it seems that nothing is gained by injection of the drug into the spinal canal, and I believe I am right in saying that this is not an established procedure in any disease.

In the great majority of cases arsanilate causes the parasites to disappear promptly from the blood and glands and not to reappear there while treatment lasts; there are however, exceptions. L. Martin and Darré had two European patients in whom the trypanosomes were insensitive to atoxyl; during its administration parasites were to be found in their blood and circinate erythema appeared; their 18 other patients reacted well to the drug. Ayres Kopke reports a case, that of a Portuguese, in whose blood trypanosomes persisted in spite of injections of atoxyl and later arsacetin. I know of a fourth case in a European (unpublished); another is mentioned by Ehrlich. Here, then, are five European cases in which trypanosomes persisted in the blood in spite of atoxyl injections, and the comparative lack of record of such an occurrence in natives is probably due to the fact that they are not so closely studied. What is the nature of this insensitiveness of the parasites? Is the resistance specific? Ehrlich and Kopke had no doubt that it was in their cases. Fortunately, such resistance is not common, and there is no evidence that a chemo-resistant strain keeps its property when transferred by an insect to a fresh individual. It is probable that serum-resistant strains—that is, strains resistant to antibodies—are of much greater importance in the treatment of man than chemo-resistant strains. We are on the threshold of our knowledge of serum resistance.

Cases of reappearance of parasites in the glands are rare. Have any cures resulted from the use of atoxyl alone? It is still uncertain. Broden and Rodhain are convinced that atoxyl can cure a large number of patients at the first stage. The members of the French Commission express themselves in the same sense. Two things must, however, be borne in mind: 1. The interval during which a patient who afterwards relapses may remain well is not yet known; G. Martin and Lebœuf record a relapse after 15 months' perfect health; trypanosomes were then found in the cerebro-spinal fluid; this was a case treated at the first stage. And Nattan-Larrier

reports the cases of three Europeans who were not treated at all: one remained well for 17 months, the second for two years, and the third for three years, after which they relapsed. It is not stated whether they were examined for trypanosomes during that period. 2. We must remember that the cases of apparent cure which have been longest under observation were treated before the atoxvl Hodges, in the report alluded to above, writes: "The number of early cases which have maintained their improvement has steadily decreased, and the number of cases likely to be permanently cured is now inconsiderable." If there are any persons who have made a recovery I would be inclined to attribute the happy event to their power of resistance rather than to the doses of atoxyl which may have been administered.

The arsanilates, and especially atoxyl, are not without their dangers; there are many recorded cases of blindness following the use of atoxyl. Much attention has lately been paid to this subject, but it is not yet clear whether the lesion is central or in the retina. The first symptom is contraction of the fields of vision; the fields, therefore, should be tested from time to time in all patients who are taking arsanilates. It is possible that persons infected with Trypanosoma gambiense are predisposed to such lesions; they have not been noticed in early cases. In Uganda all the victims seem to have been at a fairly advanced stage, and Broden and Rodhain found that of their patients who became blind all had either typical symptoms of sleeping sickness or an altered cerebro-spinal fluid; consequently they recommend a smaller dose for patients at the later stage than for the earlier cases. It seems that loss of vision is less frequent, if it occurs at all, after the use of soamin, which has, of course, a chemical formula identical with atoxyl.

How long should a course of arsanilate last? This is a difficult question to answer. Broden and Rodhain are doubtful if it is of any use to resume or continue its employment after a relapse. It must be remembered that to detect a relapse it is not sufficient to examine the blood; the cerebro-spinal fluid must be examined from time to time. There are reasons for believing that, apart from the possible development of resistance by the parasites, the prolongation of a course beyond a certain limit, not at present defined, leads to supersensitiveness on the part of the patient. In Uganda, at any rate, the administration of organic arsenicals for several months in succession has been abandoned.

When the arsanilates came into use for sleeping sickness it was hoped that they would act by killing off the trypanosomes in the body—that is to say, as sterilising agents—as they appear to do in experiments on small animals. This hope has been disappointed, probably because we are unable to give the drug in such doses as will cause the requisite concentration of the trypanocidal substance. Professor Benjamin Moore considers that the size of man, as in the case of large animals, is against his cure; he shows that the dose which can be given depends on the area of body surface, and that therefore small animals have an advantage. He believes also that the dosage depends on the area of cells lining the intestine, for these take up the arsanilate, and if the drug is present in too great concentration they are killed.

Antimony.—Tartar emetic or the corresponding sodium salt is now given intravenously to avoid the pain and reaction caused by injection into the tissues. This treatment alone is not effective for any length of time, possibly because of the rapid elimination of the drug. G. Martin and Lebœuf and Ringenbach find that though it drives trypanosomes promptly from the blood they may be present in the cerebro-spinal fluid after many injections. Injections of finely divided metallic antimony in an oily emulsion, the so-called antimony cream, are so painful that they drive away the patient as well as the trypanosomes.

There is now, I think, a consensus of opinion that two or more drugs should be employed in combination. For this course there are three reasons: 1. Experiments on animals have clearly demonstrated the advantage. 2. One can give a smaller, and therefore less dangerous, dose of each drug than would otherwise be the case. 3. The researches of Ehrlich and others show that substances of different chemical groups combine with different parts of the protozoal cell. It is interesting to note that a drug which by itself has no action may become of value when it is associated with a

powerful trypanocide; examples are mercury, and perhaps pieric acid.

Arsanilate + mercury.—Many clinicians have tried this combination. Hodges and Broden, both of whom have had much experience, consider that it has no advantage over arsanilate alone. Van Someren, who injects soamin and perchloride of mercury simultaneously, thinks that the patients so treated do rather better than those who get soamin only. No one, however, speaks very favourably of the combination.

Areanitate + orpiment is now being largely given. We are not yet able to form an idea of the value of this combination. The use of an inorganic arsenical has two recommendations: (1) some of the early cases which have made an apparent recovery were thus treated; and (2) Ehrlich's work tends to show that trypanosomes never become resistant to arsenic in this form.

Areanilate + turtar emetic.—Broden and Rodhain, as well as the members of the French Commission, speak well of this combination, which at the present moment seems to be more effective than any other. The areanilate is injected under the skin once a week, and antimony salt into a vein once or twice a week, or in series. Thiroux finds that unpleasant symptoms after antimonial injection can be prevented by the previous administration of caffeine.

To come to the new drugs—arsacetin has been used in 134 cases by Eckard in German East Africa. He finds that therapeutically it equals atoxyl, over which it has the advantage that it is much more stable. Unfortunately, blindness occurs after its use; it is noted in three cases.

P. aminophenylstibinio acid has been given once with good effect (Kopke). In injections it is too painful for general employment, but the fact that it is the antimony homologue of arsanilate makes its use promising as well as of interest.

Arsenophenylglycin is the most promising of all the organic arsenicals. We know that doses of one gramme are well borne by man, and that trypanosomes are banished from the blood and glands. More at present cannot be said. The advantage of this substance is that while the arsanilates and their derivatives have to undergo some change in the tissues—reduction, in Ehrlich's opinion—before they become trypanocidal, arsenophenylglycin is already reduced, hence its toxicity is more constant for any given species of animal, for it does not depend on the varying amount of change effected by the animal tissues.

Ehrlich has shown that to get a sterilising effect it is not necessary for all the parasites to be killed; it is sufficient if the drug so acts on that part of the trypanosome which is concerned with multiplication that the formation of new individuals ceases. He believes that arsenophenylglycin acts in this way. Here we have perhaps another explanation of the undoubted advantage of giving two or more drugs in association. One attacks the nuclear or chromidial apparatus, another the protoplasm, or, as Ehrlich puts it, they combine with receptors situated in these different parts of the cell. Ehrlich himself says that arsenophenylglycin acts much more powerfully on infected guinea-pigs if another drug (tryparosan in this case) is associated with it. Since arsenophenylglycin is likely to be soon in general use, I will echo the warning given by Ehrlich against the use of this substance, to begin with, on patients who have relapsed after other treatment. He points out that such cases are very difficult to cure, so that the reputation of a new remedy may be blasted because it is expected to perform an impossible task. Any new drug, when once its claim to trial in human therapeutics has been established by a series of successes in animal infections, should be tested on untreated selected cases at an early stage of the disease; later, of course, the relapsed or advanced cases may share the benefit.

Dyes.—Treatment by dyes has not proved of much service in the human subject, but we may yet find one which is useful. I do not think parafuchsin in combination with the more powerful trypanocides has had an efficient trial, but tryparosan (Ehrlich) promises still better results because it is more effective in animals, and tends to attenuate the virulence of the trypanosomes.

It is probable that the trypanocides, even when they do not sterilise, increase the resisting power of the organism. They may assist in the production of immunity, as has been shown by animal experiment.

Sorum.—Dr. Andrew Balfour, acting on the idea that the

cerebro-spinal fluid is lacking in trypanocidal substances, has suggested the introduction into the spinal canal of the patient's own serum, perhaps after a course of chemical treatment. The idea and the suggestion had been put forward, unknown to Balfour, by Thiroux two years earlier. We have no record of the adoption of this plan.

General measures.—One factor in treatment has perhaps been imperfectly realised—that is, the importance of increasing the resistance of the patient, especially by a generous diet. The members of the French Commission especially have emphasised this, and it is common knowledge that in times of scarcity or famine sleeping sickness becomes epidemic in places where it was previously present in an un-obtrusive form. In Busoga, a province in Uganda in which the natives reached the segregation camp in half-starved condition, the results of treatment were much less favourable than in other camps. Bödeker, in British East Africa, has treated a few cases with cod-liver oil in conjunction with soamin or atoxyl, and has reported favourably on them. Such treatment seems to me very reasonable, and I think cod-liver oil should be tried in a large series of cases. Dr. C. W. Daniels has recently called attention to the importance of increasing the resistance of the host in the protozoal as in the bacterial diseases. Similarly one must treat any condition which tends to drain the vitality of one's patiente.g., ankylostomiasis.

PROGNOSIS.

It is at present impossible to set a term to the existence of a patient infected with T. gambiense, but we are able to gauge to some extent his power of reacting to treatment and whether there is any prospect of cure. Though patients at the first stage, treated or even untreated, may recover, it is extremely doubtful whether any person has ever recovered in whose perebro-spinal fluid trypanosomes have been demonstrated either by their presence or by the change they have brought about in the constitution of the fluid. Lumbar puncture, then, is essential if we are to give any sort of guess as to the future. If trypanosomes are found, or if there are certain cell changes in the cerebro-spinal fluid, one can say this man may live for years but he is not likely to recover. Similarly the result of treatment can be checked by lumbar puncture. The patient may be improved in his general condition and be apparently well, but the result of the puncture shows that the disease is progressing towards its fatal termination. Broden and Rodhain think that treatment should be continued as long as the cerebrospinal fluid is abnormal; but that this is not a sure guide is shown by the observations of members of the French Commission who found that some cases at quite a late stage had a cerebro-spinal fluid which contained no trypanosomes and few cells. It is worth noting that the members of the French Commission were unable to find trypanosomes in the cerebrospinal fluid of 26 out of 108 advanced cases, i.e., 24 per cent. They do not say if lumbar puncture was repeated in any instance. Lumbar puncture has unfortunately three disadvantages: it is disliked by patients; the trypanosomes come and go in the fluid, so that unless the typical cell changes are present one negative result is inconclusive; and there may be a risk of introducing trypanosomes into the subarachnoid space. Ayres Kopke for this reason in a case in which trypanosomes were very numerous in the blood did not venture to puncture the membranes.

As to the value of auto-agglutination for prognosis we are in want of data. In patients who have made an apparent recovery auto-agglutination has become much less marked

without wholly disappearing.

Thiroux and D'Anfreville have found Cercopitheous patas a valuable test animal when they wished to know if trypanosomes were present or not in a patient who had undergone a course of treatment. They inject 20-40 cubic centimetres of defibrinated blood into the monkey, and again if necessary after a month; if both inoculations are negative lumbar puncture is done and the cerebro-spinal fluid injected into the monkey. Here again, for decisive information one must do lumbar puncture. If this method proves to be as reliable as its authors believe it will be very useful in tropical Africa, for the species ruber or patas is widely spread.

PROPHYLAXIS.

In the last 12 months few fresh preventive measures have been proposed. It is probable that when we know more of Glossina palpalis, its life history, breeding grounds, and dates for vacancies.

natural enemies, we shall be able to devise more effective measures for its suppression or extermination. At present we have in the main two alternatives: to avoid the fly or to clear the scrub which shelters it.

Citronella grass as a teetsefuge has lost its reputation. From various quarters comes the report that the flies do not mind it at all, and one observer doubts if it gives off any smell except when it is crushed. The members of the French Commission insist on the necessity for the use of a mosquito net, and if their belief that mosquitoes are important auxiliaries of palpalis finds confirmation, protection from these, and all biting insects, becomes absolutely necessary. They think also that all Europeans who serve in infected areas should be periodically examined, and seeing that a trypanosome infection at the beginning may be taken for malaria or some other fever this seems a wise precaution.

Roubaud, as a means of dealing with G. palpalis, recommends partial clearing or thinning of the vegetation which shelters the fig. It is generally recognised that complete clearing is not essential, that clean stemmed trees may be left if all the undergrowth is removed; but, if one may judge from photographs, Roubaud leaves much vegetation standing besides trees. His aim is to let the sun's rays reach the soil. The amount of clearing or thinning needed at any spot can always be determined by experiment, and I think it probable in some instances more is done than is necessary. On the only occasion on which I had the opportunity of superintending such work, the flies disappeared when the vegetation on half the area marked out had been cut down. This is worth remembering, for it is costly to fight jungle on a large scale.

We have learnt, I think, that the preventive measures to be adopted are not the same for all parts of tropical Africathat is to say, in one region, as Uganda or Rhodesia, it is found possible, and therefore best, to remove all natives from palpalis areas and to clear the vegetation in the neighbourhood of fords and watering places; in another, as Togoland, neither of these things can be done to a profitable extent, and it is sought to collect all the infected persons into fly-free camps; in a third it may be that a system of inspection posts is of value. Even if our preventive measures fail there are reasons for thinking that nature is slowly working—in Uganda, for instance to produce a state of toleration in the tissues of the persons infected. How this comes about, whether by an attenuation of the virulence of the trypanosome, by the weeding out of less resistant individuals, or by a combination of these factors, we do not know. To give one instance. Baker in Uganda examined in January of this year a native in whose case there was documentary evidence that trypanosomes were found in the blood in 1905. Baker found trypanosomes in his glands. This man had had no treatment and had served in the King's African Rifles for three and a half years without having ever been off duty for sickness. It is worth noting that the French Commission found marked differences in virulence of T. gambiense in man.

I have given you but a bald account of the recent advances in our knowledge of sleeping sickness. The extent of ground to be covered has prevented my straying into attractive by-paths. I think, however, that I have touched sufficient points for discussion.

University and Convocation have been notified that the University Appointments Board has now been constituted. The terms of reference to the board are "to assist graduates and students of the University in obtaining appointments, and to cöordinate and supplement the work done by the schools and institutions of the University with this object." The board hopes that members of Convocation and of the staff present and past of the schools of the University and others who are interested in its progress may be able to assist in furthering the work of the board by bringing its objects before the notice of graduates. The board desires to encourage a selection of University men for all posts where the possession of a University training on scientific methods is an advantage. Its object is to assist graduates to find employment and to assist employers to find, in the University ranks, suitable candidates for vacancies.

The Mightman Lecture

CONGENITAL HEART AFFECTIONS, ESPE-CIALLY IN RELATION TO THE DIAGNOSIS OF THE VARIOUS MALFORMATIONS.

Delivered before the Section for the Study of Disease in Children of the Royal Society of Medicine,

BY GEORGE CARPENTER, M.D. LOND.,

PHYSICIAN TO THE QUEENS HOSPITAL FOR CHILDREN; MEMBRE CORRESPONDANT SOCIÉTÉ DE PÉDIATRIE DE PARIS; VICE-PRESIDENT ROYAL SOCIETY OF MEDICINE.

GENTLEMEN,—In acknowledging the honour that you have conferred upon me by inviting me to deliver the Wightman Lecture, I must confess that the acceptance of this distinction proved far easier than the selection of a suitable subject

The coincidence of congenital malformations of the heart with malformations in other regions of the body is a matter of everyday experience. Heart malformations are not always accompanied by other congenital bodily defects, but they are sometimes found in association with such diverse structural faults as hare-lip, cleft palate, ill-developed teeth, supernumerary auricles and supernumerary nipples, polydactylism, syndactylism, webbed fingers, steeple-skull, defects in the abdominal wall, herniæ, ill-developed and absent rib cartilages, undescended testis, atresia of the anus and rectum, post-anal dimple, congenital opacity of the cornea, coloboma iris, congenital defects of the orbits, congenital ptosis, not to mention many other congenital irregularities of development which are obvious to the naked eye—cretinism, for instance—which sometimes bear them company.

Since heart malformations have been shown to be a family complaint in some instances, it must be admitted that inherited as well as acquired defects in the sperm and germ cells of the parents are of some importance in the production of malformations of the heart, as in other regions, for erratic tendencies to produce deformities when once acquired are handed down from parents to children. Inquiry has been directed to the state of the mother's health, both bodily and mental, during the pregnancy to serve as an explanation for the production of congenital cardiac defects. The heart is perfectly formed, though in miniature, in seven weeks' time from the date of conception, but various examples of congenital heart disease have been recorded by J. Lewis Smith and others, following upon frights and so on during the last two or three months of pregnancy, so it is obvious that these psychical disturbances cannot possibly have had any effect upon the feetal heart.

Several examples of fœtal endocarditis have been shown to the Society for the Study of Disease in Children or have been spoken of at its meetings. These include six cases, while a few others have been recorded by Planchu, Gardère, and André Moussous. Fœtal heart murmurs have been recorded by various writers.

It is only in a very small proportion of the cases of congenital defect that endocarditis, when it is limited to the valves, can be viewed as the cause of the disease, and such arise after the heart has been completed. The bulk of the cases of congenital malformation of the heart appear to be due to developmental errors when seen by the light of modern research on cardiac development.

Morbus caruleus and congenital malformations of the heart have been looked upon as synonyms, but without reason, for children with severe congenital morbus cordis are frequently not blue, even when excited or crying. Many verified cases of congenital morbus cordis have been recorded where cyanosis was not a symptom during life. Some children with congenital morbus cordis are fresh-coloured. Others are strikingly pale. In some the lips are dark crimson, perhaps inclined to blueness rather than redness, or to turn lilac on crying. Or the complexion may be quite good and only the fingers dusky and cold-looking. The majority, however, are cyanosed more or less, and all gradations of cyanosis may be noticed, from that of a dark rubicund face with similar coloured ears and reddened finger- and toe-tips, or a state of rather dusky-blue lips and cheeks and tongue,

and a similar condition of the extremities, to one where the face is plum-coloured, the conjunctive suffused, the buccal mucous membrane and tongue the colour of a slate, and the body generally dusky. In the majority of those who are blue the cyanosis dates from birth, but in others the children show no signs of blueness until after an attack of one of the exanthems, or following bronchitis or broncho-pneumonia, with or without whooping-cough.

By far the most common malformations of the heart in association with cyanosis are those cases where the pulmonary artery or the conus is either absent, rudimentary, or constricted. Next in frequency in the list of malformations, though only to about one-seventh of their number, is transposition of the pulmonary artery and aorta. Apart from these mal-developments, which form the bulk of congenital cardiac anomalies, the malformations which give rise to evanosis are numerous and various.

Various views have been and are still held as to the causation of the cyanosis. In many cases the explanation is suggested, not that the lungs cannot exygenate properly, but that they are prevented from dealing with a sufficient proportion of the total quantity of veneus blood throughout the body by reason of various defects in the pulmonary region, perhaps combined with weakness of the heart muscle. Cyanosis appears to depend in some cases not upon defective agration from defects in the lungs, but to be due to the conformation of the heart, which by reason of faulty construction and physical weakness is placed at a mechanical disadvantage, and is not adapted to deliver a sufficient quantity of venous blood to the lungs to be aërated. But this will not explain all cases, for in some the lungs are not healthy and display considerable microscopical alterations. So wide and so tortuous were the thickened lung capillaries in the case of atresia of the pulmonary artery I examined that those in the alveoli admitted six or more red corpuscles abreast. Changes such as these, permeating as they do the whole of the lung structure, are not conducive to proper aëration. It would appear, then, that diffuse and not localised structural alterations of the lung tissues are favourable to the production of cyanosis.

Here, then, are two factors in operation: the difficulty of getting the blood to the lungs to be aërated, and the difficulty of aërating the blood when it arrives there should it so happen that the lungs are not in a position to undertake the operation by reason of their structural defects.

Clubbing of the fingers and toes in congenital heart disease, the so-called Hippocratic fingers, depends a most entirely on congestive swelling and thickening of the soft parts of the terminal phalanges. The connective tissue is increased and the capillaries are enlarged and increased in number. The finger-tips are broadened and the nails are cyanosed, a different appearance from that shown in chronic osteoarthropathy, where the nail is domed like a watch-glass, curls over the finger-tip, and bears a striking resemblance to a parrot's beak, and is combined with osteo-periostitis of the terminal phalanx. The finger looks like a drumstick and the nail is pink coloured.

There appear to be two varieties of clubbed fingers; in one there is osteo-periostitis of the terminal phalanges, but in the other this has not yet been demonstrated. Whether there are really two varieties of clubbed fingers or whether the conditions are different stages of the same process has not yet been settled. Common as is this clubbing of the fingers and toes in congenital heart disease, nevertheless it is a feature of this disease which very often is wanting. It is in pulmonary atresia and stenosis that clubbing most commonly arises, and it is in these conditions that congestion is most frequently observed.

Ophthalmoscopic examination in cases of marked congestion reveals tortuous retinal blood-vessels of which the veins are very large. The blood in the arteries looks decidedly venous, though they are not quite so dark-coloured as the veins. The red reflex, which is of cyanosed appearance, often appears to start from the physiological pit, and the number of vessels on the face of the disc appears to be greatly increased. In children where the cyanosis amounts to but little more than a ruddy bucolic appearance, a want of the usual colour contrast between the arteries and veins is quite noticeable. The retinal blood-vessels early display evidences of congestion by enlargement and tortuosity of both arteries and veins. If there be considerable cyanosis retina, as sometimes is the case, without the associated appearance

of curly retinal vessels, such an ophthalmoscopic finding, although not proof that there is no narrowing of the pulmonary region, nevertheless suggests that the pulmonary tract is either not involved or that right-sided muscular compensation is sufficient to overcome the obstruction.

Blood changes, such as polycythæmia, macrocythæmia, and increased viscosity along with a by no means invariable increase in the hæmoglobin, are not uncommon. In one blue child under my care, aged two and a half years, with clubbed fingers and toes, who had been blue since birth, there was a blood-count of 7,880,000 per cubic millimetre, and the hamoglobin was 122 per cent. That is the largest number of red cells that I have met with in congenital heart disease. Many of the children under my care with polycythæmia have shown a deficiency in the hæmoglobin rather than an increase. In a blue infant, aged one year, with clubbed fingers and toes and lips, and finger- and toe-tips of purple hue, the blood-count amounted to 5,400,000 red cells per cubic millimetre, with a hæmoglobin percentage of 55 only.

Congenital heart murmurs are of various characters. may be heard as harsh, roaring, churning, growling, sawing, twanging, rushing, or rasping noises. Musical bruits are not common in my experience. If murmurs of such character be heard in a child under three years of age, and if they be conducted over wide areas, the presumption is strong that the affection is of congenital origin. Soft, low, very faint bruits are sometimes present. Murmurs are usually systolic, occasionally pre-systolic or diastolic, and there is that peculiar rumbling murmur carried through the systole and diastole, which points to a patent ductus arteriosus or a communication between the pulmonary artery and the aorta. Sometimes the bruits become inaudible shortly before death or during a paroxysm of cyanosis, and I have noticed a loud murmur almost to disappear under the influence of an anæsthetic. A murmur may be detected at one auscultation, and cannot be heard at the next, and the causes for this temporary disappearance are not quite clear. Murmurs are also influenced by posture and by respiration. In regard to conduction, in some instances systolic bruits may be traced along the arteries over the brachials as far as the bends of the elbows, and also be heard in the thighs along the course of the femorals. They can not only be followed up the arteries of the neck, but exceptionally can be heard by applying the ear to the vertex. In only a small proportion of the cases are murmurs absent. In my series this occurred in 7 per cent.

Thrills are not infrequent; they are usually systolic, occasionally diastolic, or even pre-systolic. These purring tremors may be localised to the site at which they are produced or be of wide conduction. Further, the site of greatest intensity by no means necessarily corresponds to the seat of production. A systolic thrill of greatest intensity at the second left interspace and conducted towards the corresponding clavicle is, however, pathognomonic of patent ductus arteriosus. A systolic thrill may be felt at the episternal notch over the aorta and be conducted into the

carotids and subclavians.

Defects in the interventricular septum are the most common of all cardiac malformations. They are associated mostly with stenosis and atresia of the pulmonary artery, transposition of the great vessels, and occlusion of the tricuspid orifice. The combination of pulmonary stenosis, deviation of the aorta to the right, and patent septum ventriculorum is one of the most usual forms of congenital morbus cordis. The commonest situation for perforate septum ventriculorum is directly beneath the aortic valves and just in front of the undefended space. In front of it lies the fleshy part of the septum and behind it the membranous. On the right side of the heart this opening will be found beneath the septal and anterior cusps of the tricuspid valve. It is rare for a perforation to be found in the anterior fleshy part. The septum may be absent, as in the cor triloculare, or the septum may be represented by a falciform ridge springing from the lower and anterior wall of the ventricle, or irregular defects may arise

Changes in the heart muscle do not necessarily follow septal defects. In some cases, however, hypertrophy and dilatation of both ventricles are seen, and this is especially likely to occur on the right side.

Defects in the septum do not always produce murmurs, but when braits are present the following characteristics have majority of cases of stenosis the interventricular septum is been noticed by me in the pure cases which have come under patent. When this septum is closed the foramen ovale is

my observation. In a child, aged two years, there was a loud rough systolic bruit audible all over the chest, the point of maximum intensity being over the pulmonary area. It was not audible in the big vessels of the neck; the second pulmonary sound was accentuated. In an infant, aged eight months, the systolic bruit was heard loudest at the junction of the xiphoid with the gladiolus on the left, and it was conducted a short way into the axilla. A faint systolic bruit was heard only occasionally at the left base. It was not transmitted to the neck vessels. The second pulmonary sound was accentuated. In an infant, aged three months, there was a loud systolic murmur at the left base, which was traceable as far as the left mid-axillary line. The second traceable as far as the left mid-axillary line. sounds were normal, and in this infant the heart was not enlarged. In the oldest child there was a marked systolic thrill all over the cardiac area, and in the child aged eight months a systolic thrill was occasionally felt at the left base, but this might have been due to the patent ductus arteriosus, and in the infant aged three months it absent.

It is not possible to lay down hard-and-fast rules as to the area of maximum intensity of the systolic bruit occasioned by patent septum ventriculorum. It is located on the left side of the sternum on the costal cartilages or interspaces, somewhere between the second left interspace and the junction of the seventh costal cartilage with the sternum, sometimes between the nipple and the left margin of the sternum, and rarely at the apex. The systolic thrill which occasionally accompanies it is not confined to any particular cardiac area; it is sometimes to be felt in the episternal notch, sometimes at the epigastrium. An important feature in the diagnosis of patent septum ventriculorum is the detection at the apex of a healthy first cardiac sound audible through the bruit and the tactile sensation accompanying it of the mitral valvular snap. The second pulmonary sound at the left base is accentuated if the pressure of the right ventricle be increased, and exceeding purity of this sound is important and suggestive.

Defects in the interauricular septum.—A patent foramen ovale is so frequently found post mortem that it can hardly be classed with other congenital abnormalities, and Fisher states that slight patency of this foramen can be found in one quarter of necropsies on adults. A widely open foramen, however, must be looked upon as an anomaly. It occurs either alone uncommonly, or frequently in association with other interauricular septal defects. Defects in the lower part of the interauricular septum are rare, and are explained by failure of the septum primum to descend and unite with

the endocardial cushion between the ventricles.

Open foramen ovale alone and along with other interauricular septal defects occurs in association with stenosis and atresia of the pulmonary artery, transposition of the great vessels, and occlusion of the tricuspid orifice. Defects in the interauricular septum happen nearly as frequently as defects in the interventricular septum. Very occasionally they are the sole lesions, and very slightly exceed in number as solitary lesions the similar conditions found at the interventricular partition.

Patency of the foramen ovale and defects in the interauricular septum are often diagnosed and seldom discovered, and for the reason that they do not often give rise to characteristic bruits-indeed, murmurs are but seldom produced by these abnormalities. Frequently cyanosis is not a symptom, though cyanosis with paroxysmal increase may be a marked feature. Gross interauricular septal defects may be carried through life without causing any inconvenience or

giving rise to any suspicion as to their presence.

Septal defects become of consequence if the auricles act unequally, and if there arises an overflow of blood into the right auricle, which produces stasis in the systemic veins. A reversal of the flow into the left auricle may bring about the same conditions by throwing extra pressure on the pulmonary artery and so on the right auricle. A point of clinical interest about defects in the interauricular septum, as in the interventricular septum, is that septic and other particles may be carried from the venous system direct to the arteries of the brain and body.

Stenosis of the pulmonary region is one of the most common of all the cardiac malformations, and in relation to atresia it occurs nearly three times as frequently. In the large

often widely open. Both of these feetal passages may remain open. In rare instances both the fœtal passages are closed. In atresia the interventricular septum is more frequently found closed than in stenosis. Of 13 cases, six of stenosis and seven of atresia, I found the ductus arteriosus closed in all the cases of stenosis and patent in all the cases of atresia except one, and in that case the lungs were supplied by a large branch from the left innominate artery and not by the ductus arteriosus as is usual. If the ductus be closed in atresia the septum will be found defective, or the septum and foramen ovale will be open, and vary rarely the foramen ovale only. When there is a defective interventricular septum the aorta, which will then be found large, is frequently transposed to the right, and this irregularity occurs more often in atresia than in stenosis. The aorta may arise from both ventricles over the defective septum, or be thrust more to the right and take origin from the right ventricle only. The stenosis may involve the whole pulmonary region. there being a hypoplasia of the pulmonary artery and its branches. In some cases the stenosis is valvular in character. It may consist of thickened nodular valve-cusps associated with a normal pulmonary artery and normal interventricular septum.

In some cases stenosis has evidently originated later in intra-uterine life, after the closure of the septum ventriculorum. In the other and the more numerous variety the forms that are met with suggest a developmental origin and a secondary endocarditis infection implanted on a rudimentary pulmonary tract.

In developmental cases the pulmonary artery is usually thin-walled and vein-like. In the other variety the pulmonary artery may be thin-walled also, but it is often either dilated or normal. In stenosis hypertrophy and dilatation of the right auricle and ventricle are common, and if the aorta be deviated to the right these hypertrophies always arise, and this vessel will be found large and thick-walled. The combination of pulmonary stenosis, deviation of the aorta to the right and patent septum ventriculorum, is the most usual of all congenital abnormalities.

In atresia the obliteration occurs at the conus, or the valve, or the pulmonary artery may be entirely absent.

Regarding the detection of right-sided hypertrophy of the heart in pulmonary stenosis and atresia a small amount of right-sided enlargement is rather apt to be overlooked if reliance be placed solely on the superficial area of cardiac dulness. Deep percussion should always be resorted to in addition, and it is well if possible to verify the result by X ray examination. The lung on the right side of the heart covers a moderate enlargement of the right auricle and ventricle and so masks the signs.

The bruit of uncomplicated pulmonary stenosis is systolic in time, and is best heard over the second left interspace close to the sternum or on the third costal cartilage. It is usually conducted over the left front of the chest and crosses the sternum, being heard slightly to the right. It is carried up towards the left clavicle. It usually ends before the axillary fold. There appears to be some doubt as to whether the bruit can be heard in the back in uncomplicated cases. It certainly can—I have post-mortem evidence as to that. It can be heard all over the front of the chest and all over the back, the left side more than the right, and also in the left axilla. It is not heard in the carotids.

Should pulmonary stenosis be associated with a patent septum ventriculorum, as so frequently happens, a systolic bruit will probably be heard in the carotids. If that be heard the suggestion is that pulmonary stenosis is combined with this septal defect, as I believe I was the first to point out some years ago. It is not necessary for the aorta to arise immediately over the septal defect to conduct a bruit into the neck vessels. The prospect of life varies in these cases according to the defect. In atresia with a closed septum the children die in infancy. If the septum be patent the child may live a few years in place of a few months. In stenosis with a closed septum middle age may be reached, but with a patent septum adult life is the limit.

Duotus arteriosus.—The average diameter of the duotus arteriosus at birth, as ascertained by post-mortem examination, is stated by Thérémin to be 4.8 millimetres, and according to Klotz this measurement is no indication of its functional capacity during life, for he states, on experimental evidence, that the size of this vessel when in action is equal to the capacity of the pulmonary artery itself.

Patency of the ductus arteriosus as an isolated lesion is rare, very few cases being recorded in the literature, but as an associate of other congenital abnormalities of the heart it is quite common. The patent duct may be cylindrical or conical, with the base of the cone on the aortic side, or globular. The lumen of the vessel in the cases that have come to autopsy has varied in size from that of a bristle we that of a finger. Hypertrophy and dilatation of the right ventricle and dilatation of the pulmonary artery commonly take place in chronic cases.

Attacks of dyspnea, epistaxis, tachycardia, and angina have been recorded by various observers in association with this condition. The characteristic rumbling mumur accompanying patent ductus has been verified by posmortem examination on adults, but not, as far as I am awar, on children. Gibson times the murmur as commencing som after the systole and gradually shading off in the long pause. Combined systolic and diastolic bruits have been recorded by Drasche and a diastolic bruit by Fagge. Systolic bruits have been described by Murray, White, Simmons, and Bittorf.

The systolic bruit is heard loudest in the second or third left interspace, close to the sternum. It may be heard only to a limited extent, or it may be carried all over the chest, back and front, and into the arteries of the neck, as in my verified cases. A thrill is by no means constant. When it occurs it is best felt in the second left interspace, and if the thrill be carried up to the left clavicle in the direction of the pulmonary artery that is pathognomonic. The pulmonary second sound may be unaltered, but if the blood pressure be raised in the pulmonary artery by hypertrophy of the right ventricle or by the contribution from the aorta, then an accentuated pulmonary second sound will be heard. If the X ray picture suggests an enlargement of the pulmonary artery, that point is in favour of patent duct. If the second pulmonary sound be loudly accentuated there will probably also be observed visible diastolic pulsation or rebound in the second left interspace at the time of the closure of the pulmonary valves.

Bruits and physical signs cannot be expected to occur in patent ducts of small calibre. In order that a bruit shall be produced it is necessary that there shall be a sufficient space within the walls of the duct and pulmonary artery, in which the conflicting blood currents shall operate best to produce vibration and sound.

Systolic bruits, in my experience, are the usual accompaniments of patent ductus arteriosus in children, and the rumbling bruit occupying the systole and diastole in adults which is considered to be characteristic of that lesion is not common in them.

Tardy closure of the ductus arteriosus may well explain the disappearance of cardiac bruits in children who have been diagnosed as suffering from a congenital heart affection. Reviewing the morbid anatomy of the congenitally deformed heart, closure of this feetal channel appears to be about the only thing possible in the way of a cure open to these cases.

Coarctation of the aorta is the name which has been given to stenosis or atresia of that vessel, either at or below the isthmus, that part which lies between the left subclavian artery and the ductus arteriosus. Soon after birth that narrow section of the aorta which is not much used during intra-uterine life is apt to be smaller than neighbouring parts of this artery, but when the circulation is reconstructed this part soon acquires its proportional relationship. describes two types. In one, the infantile, there is diffus narrowing of the aorta at the isthmus. In the other, the adult form, there is an abrupt constriction as of a cord at or near the insertion of the ductus arteriosus. The infantile type is developmental and may consist of a moderate stenosis only, or owing to the complete failure of development in regard to that part of the fourth branchial arch which lies between the ductus arteriosus and the subclavian artery. the part corresponding of the aorta—the isthmus-is represented by a cord only or completely disappears. The adult form he considers is not of developmental origin, because it does not occur in the feetus and is not met with until the closure of the ductus arteriosus, and is brought about by the act of closure of the duct itself, elements of which are incorporated in the aorta, and which by their contraction constrict that vessel as with a ligature. In the infantile type of cases patency of the ductus arteriosus is common, and in the adult type that channel is usually closed. In the adult type extensive collateral circulation is common according to

Bonnet. In the infantile type associated cardiac developmental anomalies are common and often severe; in the adult type the anomalies are usually unimportant and rarely severe. In the adult type the percentage of cases without associated cardiac developmental anomalies is far greater than in the infantile.

From the literature it appears that patients with coarctation of the aorta may live long and the condition not be suspected. In some death takes place suddenly and without obvious reason, sometimes from rupture of the aorta. Or death may occur from heart failure preceded by the signs and symptoms of mitral disease.

Congenital acrtic stenosis and atresia are much rarer than are the corresponding defects at the pulmonary artery. Conus stenosis in this situation takes the form of a thickened ring of the endocardium, just below the acrtic valves, which involves the base of the anterior mitral cusp, and is ascribed by Keith to arrest of development. The danger of this rare anomaly lies in its tendency to become the seat of endocarditis. In acrtic atresia, brought about by such conditions as obliteration at the root or by fusion of the cusps, the left ventricle atrophies and the circulation is conducted through the foramen ovale, patent septum ventriculorum, and patent ductus arteriosus. The life of such cases has been limited to a few weeks. In acrtic valvular stenosis there are two forms: one in which the septum ventriculorum is perfect, the other in which it is deficient. In this latter variety other developmental anomalies are the rule.

Aortic disease of the acquired type in children is not as rare as is commonly supposed, and some of the cases are no doubt of congenital origin. Another point of clinical interest, a recognition of which will prevent falling into error, is that aortic disease in children is apt to be associated with a bruit which is heard loudest over the pulmonary area, and not over the aortic cartilage.

Hypoplasia of the aorta is characterised by diminution in size of the aorta and arteries throughout the body, the walls of which are thin and elastic. A congenital origin has been claimed for this condition, because it is so commonly associated with anomalies in the generative and circulatory systems. A congenital tendency to the dwarfing of the arterial system had been ascribed to tuberculosis in the parents, and it may be due to other states of bad health. Hypoplasia of the aorta is associated with a dwarfed heart in some instances, and in others with an enlarged heart confined to the left side or involving both ventricles. If the heart be small during childhood it hypertrophies at puberty. The period of danger in these cases appears to belong to adolescence, when heart failure is not unlikely to occur, and this is more likely to arise under physical strain.

Defects in the auriculo ventricular valves are very uncommon. They are commonly combined with other cardiac abnormalities, uncomplicated lesions of the mitral and tricuspid valves being exceedingly rare. Of the two valves the tricuspid is more frequently attacked than the mitral, and of the lesions tricuspid atresia is the commonest.

Trouspid stenosis in association with disease of the pulmonary valves is occasionally seen.

Mitral atresia is very rare. Cases have been recorded by Rokitansky, Thérémin, and by Lawrence and Nabarro, and in each instance the condition has been associated with somatic abnormalities. A specimen of congenital mitral stenosis was exhibited at the Society for the Study of Disease in Children by Fisher in 1901. Of mitral insufficiency Cautley has afforded an example in a girl, aged 22 months. The physical signs were those of mitral regurgitation, and another case in a boy, aged 10½ months, has been quoted by Maude Abbott.

Hypertrophy of the heart undoubtedly arises as an idiopathic disease of congenital origin. Simmons was the first to record a case of its existence at birth. He found the heart of a newly born child, who died during the labour, to be enlarged to twice its natural size, all other organs of the body being quite healthy. Prior to that Hauser had recorded a case in a baby, aged 11 months, in which the heart was enormously dilated, with hypertrophied right and left ventricles. Virohow suggested that the hypertrophy might be congenital.

Cardiac displacements such as dextrocardia and mesocardia are the only congenital malpositions that are of interest to the physician and therefore that need be reviewed. Dextrocardia accompanied by transpositions of the viscera is commonly viewed rather as a rare developmental freak than recognised, as should be the case, as a not very out-of-the-way clinical

experience. Dextrocardia without associated transposition of the viscera is rare, and not only is it rare, but it must be viewed with suspicion because the diagnosis of congenital dextrocardia has been made on some few occasions, and this opinion has not been confirmed by necropsy.

Sometimes the position of the feetal heart in the centre of the thorax is maintained, giving rise to the condition known as "mesocardia." The apex beat will then be felt in the epigastrium, and the position of the organ will readily be demonstrated by the X rays.

CHRONIC GLANDERS IN MAN WITH REFERENCE TO AN UNUSUAL TYPE AFFECTING THE UPPER RESPIRA-TORY TRACT.*

BY O. L. ADDISON, M.B., B.S. LOND., F.R.C.S. ENG., SURGEON TO OUT-PATIENTS, HOSPITAL FOR SICK CHILDREN, GREAT ORMOND STREET; LATE SURGICAL REGISTRAR, UNIVER-SITY COLLEGE HOSPITAL;

AND

G. SECCOMBE HETT, M.B. LOND., F.R.O.S. ENG.,
SURGEON LARYNGOLOGIST. MOUNT VERNON HOSPITAL FOR CONSUMPTION
AND DIBEASES OF THE CHEST; ASSISTANT SURGEON,
THROAT HOSPITAL, GOLDEN SQUARE.

SINCE the publication in 1830 by Elliotson of the first undoubted case of chronic glanders in man the recognition of this condition has become increasingly frequent, and in 1906 Robins 2 of Montreal collected 156 cases, including one of his own which was the first reported case occurring in Canada. After a careful study of these cases and of a few others which have since been recorded, the striking characteristics appear to be, firstly, the great variability of the manifestations: secondly, the extreme difference in duration both of the incubation period and of the periods of latency or quiescence which occur during the course of the disease; and thirdly, the similarity of the manifestations to those of syphilis and tubercle. In about 40 per cent. of the collected cases there was ulceration of the nasal, buccal, or pharyngeal mucous membrane at some time or other during the course of the disease, but in only three of these was it a salient feature, while in one case alone was it the sole lesion at the time when the patient came under observation. This case was that of a patient at the Westminster Hospital under the care of Mr. A. H. Tubby in 1904-05. We have, however, recently had the opportunity of observing a similar case for a little over a year, and feel that it is worthy of being somewhat fully recorded, both on account of its rarity and because of the importance of making a correct diagnosis. The difficulty of diagnosis in this class of case lies in the close resemblance between this condition and tertiary syphilitic ulceration of the buccal and pharyngeal cavities; indeed, both in Mr. Tubby's case and in our own case the patients were treated for syphilis for a considerable length of time.

CASE 1 (Mr. Tubby's case).—The patient, a carman, aged 22 years, was first seen in May, 1904. "Symptoms had then been present for nine months. At this time the soft palate was entirely destroyed; the hard palate was perforated, and there was a widespread granular erosion of the oral and nasal pharynx. On the lateral aspect of the dorsum linguæ was a soft discrete swelling, walnut size. There was no history or evidence elsewhere of acquired or congenital By December, 1904, the ulceration had spread considerably, involving the anterior part of the tongue, but for a month or two the progress of the disease seemed to be arrested, and the patient's general condition improved. temperature curve for 9 weeks showed an almost uniform daily intermission of 2° or 3°, but for the last month or two of his first stay in hospital was almost within normal limits." In January, 1905, a diagnosis of glanders was made. Previous to this the patient had been treated for syphilis. By April, 1905, a considerable part of the alveolar border of the upper jaw was destroyed. Almost the whole of the anterior third of the tongue was destroyed; the right antrum of Highmore was invaded. The patient died from "exhaustion" in August, 1905.

^{*} The superior figures occurring in this paper refer to the bibliography printed at the end.

CASE 2.—On August 8th, 1908, the patient, a carman, came to the out-patient department of University College Hospital, where he was seen by one of us. He was complaining of "sore-throat." The patient was a slightly built man, "sore-throat." The patient was a slightly built man, appeared thin and wasted, but did not look acutely ill. On inspection of the mouth extensive ulceration of the palate and pharynx was visible. This had completely destroyed the uvula and also the posterior half of the soft palate. The tonsils and fauces were entirely destroyed, with the exception of a part of the anterior pillar and a small piece of tonsil on the left side. The ulceration was beginning to invade the alveolar border of the lower jaw on the right side, with extension on to the cheek. There were also one or two small isolated ulcers present on the remains of the soft palate, due to the breaking down of small abscesses. These ulcers were not raised above the general surface of the palate and their edges were very thin and undermined. The main ulceration was continuous over the palate and fauces. There was very little sign of inflammation, the margins not being discoloured and only slightly swollen. The edge was extremely irregular and a little undermined, while the floor was covered to a large extent by sticky muco-pus. The visible part of the posterior pharyngeal wall opposite the base of the tongue was covered by scar tissue, a prominent band of this running almost transversely across. On posterior rhinoscopy, the septum and turbinals were seen to be swollen and covered by tenacious pus, which also covered the Eustachian cushions and orifices, but there was no ulceration. vault and upper part of the naso-pharynx were covered by thick crusts. On removal of these the condition was seen to be similar to that of the lower part of the posterior pharyngeal wall, the mucous membrane being replaced by cicatricial tissue. On anterior rhinoscopy, a septal deviation and enlarged anterior end of the inferior turbinal were found blocking the right nostril, the left being widely patent and the mucous membrane reddened. There was no ulceration on either side. On laryngoscopic examination nothing abnormal was found. There was no enlargement of the submaxillary or cervical glands. Nothing abnormal was found in the heart and lungs. A small scar, the result of an abscess, was present on the back of the left forearm. No evidence of syphilis, congenital or acquired, could be found on careful search.

The case was diagnosed to be one of chronic glanders, and this diagnosis was strongly supported by the following facts, which were elicited on questioning the patient. He first felt ill in August, 1907, when he was seized with violent cramps in the legs, pains in the back and limbs, and severe headache. He was taken to Charing Cross Hospital. On questioning the patient as to the condition of the horses under his care at that time, he said that the horse he was driving when he was taken ill "had a mattery discharge from its nose and large lumps under the jaw." He further learnt that four days after his admission to hospital (Charing Cross) this horse was removed from the stable and destroyed. His informant thought that it was suffering from glanders.

The patient was admitted to University College Hospital under the care of Mr. W. Trotter and was isolated. following history was then compiled from material obtained from the Charing Cross Hospital. On August 13th, 1907, the patient was admitted to that hospital, remaining there till Sept. 6th. His illness dated from August 8th, when he was seized with violent cramps in the legs, pains in the back and limbs, and severe headache. During his stay in the hospital these continued but gradually diminished in severity. abscess developed on the back of the left forearm and on August 27th this was opened. Cultures from the pus proved sterile. The temperature ran a febrile course but gradually came down to normal. The case was thought to be one of influenza with intramuscular abscess. On Jan. 10th. 1908. the patient returned to Charing Cross Hospital and attended the throat department with an ulcerated throat which was considered to be syphilitic. He gave a history that for about six weeks he had found that liquids came back through his nose. At this time there was extensive ulceration of the naso-pharynx and tonsils, with loss of the anterior pillar on the right side. There was no ulceration in the nasal cavity. He attended till Feb. 18th, when he went to the infirmary, where he remained till August 8th, on which day he came to University College Hospital. While in the infirmary he was treated for syphilis, but without benefit.

On admission to University College Hospital on August 8th,

1908, bacteriological investigations were at once commenced. Cultures on potato were made with pus from one of the isolated ulcers on the soft palate, and also from a small piece of the ulcerated border. A non-Gram-staining organism was grown, which when injected intra-peritoneally into a male guinea-pig produced orchitis, but conclusive evidence of glanders was not obtained. While in the hospital the patient was treated with mouth washes and large doses of mercury and potassium iodide, bacillus mallei not having been found. His general and local condition improved somewhat, the ulcerated area becoming cleaner and showing evidence of healing in some places. The temperature at first was very irregular, rising to 102° F. or more at night, and coming down to normal in the morning, but after three or four weeks it became more regular, with only an occasional rise of one or two degrees. He was discharged on Oct. 24th, but continued to attend as an out-patient in the Throat Department, under the care of Mr. H. Tilley. In December, 1908, the case was shown at a meeting of the Laryngological Society, when the consensus of opinion was in favour of the diagnosis of refractory syphilitic ulceration of the upper respiratory tract. A Wassermann's reaction was done by Professor Lieven of Aix-la-Chapelle, who confirmed the diagnosis of syphilis on clinical examination, but was surprised by obtaining a negative result by the test. The patient continued to attend the ear and throat department of University College Hospital until May, 1909, when both the general and local conditions were much worse.

In June, 1909, he was admitted to the Throat Hospital in Golden-square. On admission he was found to have two abscesses, one subcutaneous, below the angle of the jaw on the right side, and the other pointing under the mucous membrane of the right cheek, while the ulceration of the palate had progressed considerably. The abscess below the jaw was opened and cultures were made from the pus. A non-Gram-staining organism was again obtained and of 2 male guinea-pigs injected, 1 died with orchitis. A section from the ulcerated edge of the palate showed chronic inflammatory changes. Owing to the closing of the ward he left the Throat Hospital, and on July 26th, 1909, was readmitted to University College Hospital under Mr. Bilton Pollard. A few days previously he had a considerable hæmorrhage from the palate.

On admission the patient was very pale and much wasted. On the right side of the neck was now a small, shallow, irregular ulcer, the remains of the abscess opened while the patient was at Golden-square. The edges of this were thin, congested, and undermined, and some thin, yellowish ous was escaping. On both sides of the face over the lower jaw were small abscesses; that on the right side was covered with thin discoloured skin, the skin over the other being very little affected. There was scarcely any inflammation around either abscess. There were no enlarged glands on either side of the neck. The ulceration in the mouth had by this time entirely destroyed the soft palate with the fauces on either side, and was spreading forwards on to the cheeks and alveolar border of the lower jaw on both sides. The ulceration on the hard palate had spread until it reached the alveolar border, and granulations were present between and around the teeth. On anterior right side, however, was filled with pus, and on the lower portion of the septum was an oval ulcer extending backwards on to the spur, the ulcer having a sloughy base and somewhat overhanging edge. The inferior turbinal was red and granular in appearance and touching the spur. On posterior rhinoscopy the mucous membrane on either side of the septum was swollen and a small ulcer was present on the left side of the posterior border of the vomer. The posterior ends of the middle turbinals were hypertrophied, and on the posterior end of each inferior turbinal was a small ulcer. The vault of the pharynx presented practically the same appearance as in August, 1908. There were some granulations in front of the left Eustachian orifice. On laryngoscopy the epiglottis. larynx, and base of the tongue were unaffected. No abnormal physical signs were detected in the lungs.

On August 3rd the abscesses in the face were opened and thick yellowish pus was evacuated. "From this pus four cultures were made on potato. Growth was visible on August 6th in one of the tubes, and on the 7th half a dozen separate colonies were present. Microscopic examination of

this growth showed a picture indistinguishable from that seen with an undoubted glanders culture. Three subcultures were made from the primary culture on August 7th, and each had a visible growth on the 9th, apparently quite pure. From one of these cultures two male guinea-pigs were inoculated intraperitoneally on the 9th, and also fresh subcultures made. On the 12th there were signs of orchitis in both guinea-pigs, and on the 16th one was chloroformed to death and a post-mortem examination made. There were no apparent lesions of the abdominal or thoracic viscera, but there was extensive ulceration of the tunicæ vaginales of the testicles, and the testicles were partly adherent to the scrotum. Microscopic examination of the pus showed the presence of bacilli with the morphological characters of glanders bacilli, and cultures made on the 16th, using the pus as seed material, had a visible growth on the 19th, and this growth had all the appearances of a glanders growth, both macroscopically and microscopically. Single colonies also appeared on Angust 8th in two more of the original tubes." These bacteriological investigations were made at the Royal Veterinary College, Camden Town, by Mr. A. Leslie Sheather, to whom we wish to tender our best thanks.

While in hospital the patient's general condition improved somewhat, although the palatal ulceration continued to spread. Two or three pretty severe hæmorrhages occurred from the separation of sloughs in the naso-pharynx, and a small oval perforation appeared in the hard palate. The ulcers on the face pursued a very chronic course, but were scabbed over by Sept. 2nd. The temperature varied from 102° to 97.4°, rising every two or three days, and usually falling to normal within 12 hours.

Chronic glanders is notoriously difficult to diagnose, but there are, however, in the majority of cases some features which, although when taken singly are of small value, yet collectively are of the greatest importance in making a diagnosis; these are: 1. Occupation. In nearly every case of chronic glanders the patient has worked at some period among horses. 2. History. (a) Of a febrile attack of uncertain nature at a variable period before the onset of the symptoms for which the patient seeks treatment. Such an attack occurs in 40 per cent. of cases of chronic glanders (Robins) and has been most variously diagnosed. subcutaneous and intramuscular abscesses. These have been found to occur in 83 per cent. of cases (ibid.). (N.B. The scars resulting from these abscesses have frequently been mistaken for the result of syphilitic lesions, as in a case described by Besnier. () 3. Type of ulceration. In a considerable proportion of the cases where palatal ulceration is found it is quite indistinguishable from that of tertiary syphilis, but in some cases, of which our own is an example, the process seems to be much more one of simple melting away of the tissues than of granuloma formation with subsequent necrosis, such as occurs in gummata. 4. Temperature. A daily variation of 2 or 3 degrees or more is an almost constant feature. In our own case the temperature was much more of a tertian type, and Hallopeau 5 notes the same fact. 5. Presence or absence of undoubted signs of syphilis such as interstitial keratitis or old periosteal nodes. 6. Reaction to anti-syphilitic treatment. Improvement in chronic glanders is said to have occurred in a few cases under mercurial treatment, and in two cases recorded by Gold a cure is said to have resulted. In the majority, however, no improvement results.

A diagnosis can generally be arrived at on careful pathological investigation, but the following sources of error have to be borne in mind:—(a) In examinations of sections from the edge of an ulcer glanders bacilli are few in number and difficult to recognise, the reason, according to Sir J. McFadyean, being "the rapidity with which nuclear destruction takes place, and the persistence with which the nuclear fragments remain as deeply staining débris, rendering the attempt to identify the bacilli in sections very unsatisfactory." (b) The intraperitoneal inoculation of guinea-pigs with pus direct from an ulcer or abscess is liable to be inconclusive owing to the animal not developing orchitis at all or else dying from general peritonitis before orchitis has time to develop. To obtain conclusive evidence from Straus's reaction it is necessary to make an injection from a culture grown (on potato) with pus from the suspected patient. Omission of this precaution was the Omission of this precaution was the cause of the first failure in our own case. (c) An adult male guinea-pig should be used for the inoculation. Bernstein

quotes Nicoll, who proved experimentally the marked vulnerability of the tunica vaginalis of the adult male guinea-pig, the greater resistance of the female, and the still greater resistance of the young male.

General Remarks.

Mode of infection.—In the majority of cases this occurs through a wound or abrasion of the skin, but in a certain number the infection appears to be through the mucous membrane of the mouth or nose. Whether a previous lesion is necessary or not is uncertain.

Inoubation period.—This appears to vary from a few hours to a year, the most usual period being four to seven

davs.

Latency.—Long periods of freedom from any manifesta-tion are a striking feature of chronic glanders. In Hallopeau's case there was an intermission of three years, while Babés 10 mentions the case of a groom who caught the disease from glandered horses, apparently recovered, and lived for five years to all appearances quite cured in a region where there were no horses but only oxen. At the end of this time he developed multiple refractory abscesses and signs in the lungs, dying a year later. Bacillus mallei was found at the necropsy. Von Baracz 11 also mentions a case with five years' freedom from symptoms.

Variety of manifestations.—This variety is marked in the initial stages, and continues throughout the course of the disease. Typhoid fever, septicæmia, pneumonia, and rheumatism are a few only of the diagnoses which have been made at the onset; the initial rash when present has most often been mistaken for that of small-pox. The later manifestations simulate nearly all those of syphilis and tubercle, from gummata to osteo-myelitis and meningitis. 12

Duration of the disease. - It is difficult to give the average duration, but a considerable proportion of cases die within four months. There are, however, numerous instances where the patient has lived for two or three years, while there are we recorded cases of six and one of 15 years' duration. 12

Prognosis.—It has been estimated that about 60 per cent. of the chronic cases recover. This figure is certainly in excess of the true one, in view of the fact that many cases are considered cured and lost sight of immediately afterwards. Seeing, however, the long periods of latency recorded, it is most likely that a certain percentage relapses. Babés 13 states that he had repeatedly recognised in the lungs of those who had dealings with horses, and who had died from other diseases, old, sometimes partially calcified, tubercles which he had been wont to attribute to tuberculosis or syphilis, but in one such case he found the B. mallei culturally, the man having died from chronic nephritis. (See also Zieler. 14)

Treatment.—Treatment of any kind has so far seemed to be of little avail. Bonomé 15 reports a case where "improvement" followed injections of mallein, while Gold records two cases which he considered were cured by mercurial inunction. Possibly some good may result from a vaccine treatment.

Both the cases reported above show very well the remarkable resemblance of chronic glanders in this form to tertiary syphilis. Clinically there was little in either of them to suggest a diagnosis other than that of syphilis, and, indeed, both of them were treated for that disease for long periods. In our own case a diagnosis was arrived at through a recollection of Mr. Tubby's case, which was shown at the Clinical Society of London in 1904. These two cases appear to represent a clinical type of the disease not previously recorded. In Mr. Tubby's case the patient had ulceration of the buccal mucous membrane for 15 months, and then developed multiple subcutaneous abscesses shortly Our own case had similar lesions for 18 before death. months before developing abscesses. Both cases show a temperature typical of chronic glanders. In Mr. Tubby's case no history of acute illness was obtained, but in ours, in common with most other cases of chronic glanders, this was present. It seems possible that this clinical type may be commoner than has been supposed, owing to the absence of other lesions, and may account for some of the cases recorded as intractable syphilis of the upper respiratory

The importance of making a correct diagnosis between a disease which is infectious and usually fatal, and a condition which is practically non-infectious, need not be emphasised.

Several cases are on record in which chronic glanders has been transmitted from man to man, the most striking instance, perhaps, being that reported by Batko, 10 where a man suffering from chronic glanders infected his wife and two children, all four dying. Note, also, the case quoted by Von Baracz, 17 of a surgeon who died from acute glanders through pricking his finger whilst operating on a suppurating knee-joint in a colleague suffering from the chronic form of the disease.

We wish to express our thanks to those gentlemen under whose care our patient has been for permission to make use of their notes.

of their notes.

TWO INTERESTING BILHARZIAL CONDITIONS.

By FRANK COLE MADDEN, M.D. MELB., F.R.C.S. ENG., PROFESSOR OF SURGERY, EGYPTIAN GOVERNMENT SCHOOL OF MEDICINE; SENIOR SURGEON, KASE-EL-AINY HOSPITAL, CAIRO.

As our clinical knowledge of the widespread ramifications of bilharziosis throughout the body becomes more exact, we are beginning to recognise certain peculiar limitations of the disease in particular organs and tissues; and, as a result of this increased knowledge, our treatment has become much more radical and effective. And this, too, in cases that fermerly appeared beyond any reasonable operative interference short of actual mutilation. In this connexion I would like to record my recent experiences with two bilharzial conditions, in which the results obtained have been very satisfactory—a distinctly encouraging fact in view of our almost hopeless struggle in the treatment of the more advanced degrees of bilharziosis in other parts of urinary and intestinal tracts.

Bilharziosis appears to manifest itself very lightly outside of Egypt; for a recent writer states that in a long experience of the disease in Natal he has never seen a fatal case. Egypt, on the contrary, the disease appears to attain the highest level of pathological activity; and the records of Kasr-el-Ainy Hospital, prepared by Dr. H. B. Day, show that, of a total of 3400 admissions for medical and surgical diseases, in 1907, there were 158 cases of bilbarziosis; and, of this number, 50 cases were unrelieved and 23 died, a mortality of over 14 per cent.; while, in 1908, of 4003 admissions, 281 were cases of bilharziosis, of whom 45 were unrelieved and 25 died, a mortality of almost 9 per cent. Taking the two years together there was thus a certain mortality of 10 per cent. But this does not nearly represent the true death-rate, as many patients are taken out by their friends in a moribund condition, so great is the native prejudice against dying in hospital. Nor does the number of admissions give much idea of the frequency of the disease, as many cases are treated as out-patients, being either in the early stage of the malady or unable to find room in the wards. Last year, notwithstanding, 7 per cent. of the total admissions for medical and surgical diseases were bilharziosis.

The two conditions to which I wish to refer are: (a) bilharziosis of the penis; and (b) what was to me a new manifestation of the disease, bilharziosis of the anus and surrounding tissues.

BILHARZIOSIS OF THE PENIS.

By far the greater number of cases of bilharziosis of the penis are associated with bilharziosis of the urethra, with or without urethral fistulæ; but there are certain examples of what may be called primary bilharziosis of this organ, to which attention will first be directed.

1. Bilharzial deposits in the erectile and subcutaneous tissues of the penis. - In certain cases there may be "a deposit of bilharzial tissue, in the form of a hard lump, in the corpus spongiosum or even in the corpora cavernosa, which can sometimes be completely removed by operation and which are then seen to have no connexion with the urethral canal." It is only the presence of bilharziosis in other parts of the body and the microscopical examination of the specimen that enable one to make a positive diagnosis. These masses produce no symptoms other than those of inconvenience, and in time tend to soften and reach the skin or urethra. times, again, an external sinus leads down to a hard mass of similar characters, but without any urethral communication. Similar lumps may be found immediately beneath the skin of the penis, usually on the under surface, and may be removed in the same way. These subcutaneous deposits may occur in other situations, particularly in the region of the perineum and anus, and ultimately may develop into typical bilharzial sinuses or give rise to a slowly spreading irregular ulcera-tion; but I have never seen this ulceration occur on the penis, except on the glans, where, sometimes as a result of infiltra-tion of this part, there are shallow worm-eaten areas or numerous small patches of atrophic scarring. When a more definite ulceration does occur either in the glans or at the meatus it appears to remain quiescent for some time and then suddenly to take on an epitheliomatous growth.

2. Bilharziosis of the glans penis and prepuce.—A peculiar bulbous condition of the end of the penis is sometimes met with, in which the whole severity of the disease seems to vent itself on the glans, the prepuce, and the first inch or two of the urethra. The surface of the glans is dry and pitted or patchily covered with shallow atrophic scars; while, from bilharzial infiltration and obstructed lymphatic circulation, the substance of the glans becomes swollen and hard and merges into a similarly hard swollen prepuce, which forms a very distinct collar of solid ædema, sharply separated by a deep furrow from the body of the penis. This furrow is usually in the site of the circumcision scar. As a result of the solid swelling all round it, and, also, of a bilharzial deposit in the mucous membrane of the urethra, the external meatus becomes very much constricted and there is considerable difficulty in introducing even the smallest sound. The actual orifice of the urethra may be eccentrically placed, owing to the scarring around it and the involvement of the frænum of the prepuce in the solid cedematous change. Once the sound has passed the constricted portion of the urethra it goes on into the bladder without further difficulty. There is frequently a discharge from the meatus in these cases which may be mistaken for gonorrhea, the swelling of the glans and prepuce being ascribed to an accompanying inflammation of these structures. In these localised cases there are usually no fistulous tracks and only a very limited extent of urethral infiltration. This latter statement was proved in a particular case, as a partial amputation of the penis was performed, in our ignorance, and, to the naked eye at all events, the mucous membrane in the stump was quite normal. Hitherto in such cases a partial amputation has been practised, but in future I should certainly attempt the removal of the swollen prepuce only, as will be described later, at the same time adopting the necessary measures for the effective treatment of the meatal stricture. These milder degrees of bilharziosis of the penis occur almost entirely in boys, which makes it even more imperative to adopt

conservative measures if possible.

Of the more definitely secondary conditions the most common is—

3. Bitharziosis of the glans, prepuce, and body of the penis.—
In these cases, in addition to the lesions just described, the skin and subcutaneous tissues of the body of the penis are also involved. Behind the deep furrow at the circumcision scar the penis may be swollen to almost any extent, with the same peculiar solid cedema, which often only extends to the root of the organ, being here limited by another deep furrow. Cases of this kind are frequently associated with bilharziosis of the urethra, but not all of them, and running through the swollen tissues are numerous urinary fistulæ. In one case of this nature there are several penile fistulæ, communicating with the anterior

portion of the urethra. Such fistulæ are generally found on the under surface and open into the urethra at the posterior margin of the glans. In this particular case there is also a peculiar silkiness of the skin of a somewhat enlarged scrotum from partial lymphatic obstruction at its neck. This appearance is not uncommon in this condition. In more advanced cases the urethra is much more extensively affected and numerous fistulæ run irregularly through a mass of false elephantiasis tissue, which not only involves the penis and its coverings but extends to the scrotum and perineum and surrounding parts. In a case of this kind the fistulæ open mainly into the perineal portion of the urethra and less frequently into the penile part. In fact, the clinical picture is rather that of bilharzial urinary fistula than that of bilharziosis of the penis. The testicles are usually quite unaffected, though long tracks may run in the soft tissues of the scrotum and perineum in all directions.

Treatment.—In my earlier cases it was my practice to amputate the penis behind the mass, if possible, and to send the more advanced cases out as inoperable. I am now convinced that in most cases these mutilations are quite unjustified unless an epitheliomatous condition exists, and I now proceed to dissect out the body of the penis from its enveloping sheath of swollen tissues. The operation is similar to that practised for elephantiasis of the penis and consists in a free dorsal incision extending from beyond the limits of the swelling above to the posterior margin of the glans below. The incision is deepened till the loose connective-tissue space between the subcutaneous tissues and corpora cavernosa is opened up. Working in this space laterally in both directions, with a catheter in the urethra as a guide, the whole of the swollen tissue is completely removed, leaving only the glans and the erectile tissue. Fistulous tracks, if they exist, are cut off flush with the urethra, their opening into which is thoroughly scraped. The large raw surface is dressed for the first few days with protective and later with red lotion. When granulation has commenced, skin grafting by Thiersch's method is practised and the new skin sheath rapidly forms. The glans gradually becomes smaller and the fistulæ slowly heal. Even in the localised form of the disease the ring of swollen prepuce may be dissected off and the surface subsequently grafted and an attempt made to dilate the strictured meatus by incision and subsequent dilatation. Any fistulæ are treated as may be necessary. Î wish particularly to advocate this conservative treatment in these cases, and to record my satisfaction of the results obtained by its adoption. The number of cases so far is small—the condition is not a common one; but if such cases as we have had can be treated successfully in this way it would indeed be a remarkably advanced one that could not.

4. Bilharziosis of the glans penis ending in epithelioma.—As has been already incidentally mentioned, a bilharzial infiltration of the glans penis may give rise to a superficial ulceration. This in time progresses by easy stages until it becomes definitely malignant. Here there is usually an extensive infiltration of the urethra with bilharzia, and in a comparatively short time a rapidly spreading epithelioma develops, with secondary glands in the groins and all the ordinary concomitants. Kartulis has published cases of this nature in which he has found many ova among the epithelial downgrowth. Naturally nothing short of a very prompt and cadical operation is possible in these circumstances.

BILHARZIOSIS OF THE ANUS AND SURROUNDING TISSUES.

I have recently had two cases under treatment at the same time of the above condition, another unusual phase of this many-sided disease and one which is quite new to me; they are the only ones I have seen. The patients were both prematurely old men with a long history of bilharzia in the urinary tract, but without any symptoms of intestinal infection. The urinary signs gradually disappeared and gave place to those of prolapse of the rectum, which preceded by some time any actual tumour. Constant tenesmus with difficult and painful defecation were now the principal symptoms, and a good deal of muco-purulent discharge came away with and after the motions. One patient complained of occasional bleeding, but it was not at all a prominent symptom. On examination a hard localised mass was found completely encircling the anus and involving the mucous surface well above the sphincter muscle. No bilharzial papillomata could be felt or seen, and the mucous membrane was perfectly smooth and

not ulcerated. Laterally the mass extended well out on each side into the ischio-rectal fossæ, but could be freely moved in all directions with the anus as its fixed point. On closer examination the lump was seen to consist of much thickened epithelium, in which were deep tracks running for some distance irregularly into the tumour, but having no communication with the rectum. The white sodden epithelium around the orifices of these pits, and the thick, dirty sebaceous-like discharge exuding from them made one think they were sinuses; but on subsequent dis-section it was quite evident that these pits were simply formed by an infolding of a normal, though thickened, epithelium and that nowhere did they communicate with each other or with the rectum. In the midst of the mass was the distorted opening of the anus, resembling somewhat the urethral orifice in the much elongated prepuce of a case of elephantiasis of the penis and scrotum. The tumour itself was very hard but gave no impression of malignancy, nor were there any enlarged glands in the groins. The provisional diagnosis of bilharziosis was made on the presence of the disease in other parts and the resemblance of the growth to somewhat similar appearances of bilharzial papillomatous-like masses about the female genitals.

Under stovaine anæsthesia the mass was completely removed by a circular incision well beyond its limits all round, and finally cutting across the rectum above the growth. The cut edges of the gut were then sutured all round to the surrounding fat, in the hope that contraction would occur later and assist in the formation of a sphincter. No attempt was made to close the rest of the raw surface, and after some weeks it had become firm scar tissue around a much smaller rectal orifice, and both patients regained practically perfect control over their motions.

The mass on section displayed the nature of the epitheliallined sinuses very well, and for the most part consisted of a much hypertrophied and redundant epithelial covering and a dense fibrous bilharzial tissue. The absence of fistulæ and ulceration on the mucous membrane was remarkable, in striking contrast to the chronic bilbarrial ulceration in this situation which in other cases not infrequently ends in epithelioma. The absence, too, of any naked-eye bilharzial infiltration of the rectum is another interesting feature.

A CASE OF LATE RICKETS (?) IN A PREVIOUSLY HEALTHY CHILD AGED THIRTEEN YEARS.

By FRANCIS HERNAMAN-JOHNSON, M.B., CH.B. ABERD.,

ROYAL NAVY (RETIRED); LATE SURGEON, ROYAL NAVAL HOSPITAL, PLYMOUTH.

IN THE LANCET of Nov. 10th, 1906, there appeared a report of an address on Adolescent Rickets, given by Mr. H. H. Clutton to the Clinical Society of London. He quoted at some length a typical case, the photographs of which show striking deformity. As a result of his observations, Mr. Clutton concluded that this somewhat rare disease must be regarded as pathologically identical with infantile rickets; and, so far as I can gather, this appears to be the most generally accepted view to-day. The following case, occurring in my own practice, I venture to publish as being of interest in connexion with this subject.

The patient, a girl, was just under 14 years of age when she first came under my care. Her parents gave me the following history. Until the age of 13 years the child had been remarkably healthy. She had helped her father in the fields—he was a small farmer-and had distinguished herself in games at school, winning several prizes for running and jumping; but with the beginning of menstrual life there had come a change. The girl, though not apparently suffering in her general health, began to have difficulty in walking, and it was noticed that her legs, especially the right, were beginning to bend outwards. She was taken to a "bone-setter." This gentleman declared, after the manner of his kind, that both hips were "out," and he proceeded forthwith to in." So powerful is imagination. out them So powerful is imagination backed by faith that the parents avowed the child was better for some weeks after these manipulations. However this may be, they presently

took her again, and were now told to go and get "irons." Irons were accordingly obtained and the patient wore them for some months. In the meantime the deformity continued to increase and the apparatus became so painful that it had to be discarded. It was at this stage that I was called in.

Physical examination showed that there was some measure of justification for the bone-setter's diagnosis. The patient walked with a peculiar waddling gait, which closely simulated that of double congenital dislocation, and there was slight lordosis present. Nevertheless, a careful examination of the joints, combined with the history of the case, convinced me that there was not, and never had been, any dislocation. The legs were markedly bowed, the thighs curving out from the pelvis to such an extent that when the child stood with heels together and toes at an angle of 45° there was a gap of six inches between the knees. The right tibia bulged outwards suddenly as it neared the ankle-joint; the left was fairly straight. The pelvis appeared normal. There was slight left dorsal scoliosis, compensated by right lumbar divergence, and the girl was round-shouldered. The parents declared that her back, like her legs, had for 13 years been perfectly straight. For the rest, the patient seemed to be in fair health and spirits, possessed of a good appetite, and free from digestive disturbances. The leg and thigh muscles were well developed and powerful. There was no tenderness in the pelvis, lower limbs, or elsewhere.

Menstruation seemed normal; the urine presented no peculiarities; pyrexia was absent. Examination of the thyroid region revealed nothing. Apart from the spinal curvature, which, as above mentioned, was stated to be recent, there was nothing to suggest that the child had ever suffered from infantile rickets-no beading of ribs, enlargement of radial epiphyses, or pigeon chest. Nor could I obtain a history of any of the symptoms of early rickets. Measles and chicken-pox formed the sum-total of her previous ailments.

Treatment.—As iron supports had been tried and found wanting, I ordered the patient to rest for six months. The mischief done by gravity might, I hoped, be overcome by a steady force in an opposite direction, and I therefore had a special apparatus constructed by an instrument maker. The patient lay on a hair mattress. Above the waist she was made as comfortable as possible with cushions, but from the buttocks downwards her body rested on a narrow platform of boards about 3 feet long by 18 inches wide. This was furnished with a perpendicular foot-piece to which the feet were strapped, heels together (with a pad between to prevent soreness), the toes spreading to an angle of about 45°. Around the waist was fitted a belt resembling a portion of a corset; from this a strip of canvas 2 inches wide was passed down on the outer side of each leg to be attached to the foot-piece below. Six bands, 2½ inches wide, consisting partly of canvas and partly of elastic webbing, and furnished with straps and buckles, were passed round both limbs at regular intervals from the thighs to the feet. They were held in position by passing through loops stitched to the side pieces, and it was possible by tightening the straps to exercise a graduated pressure in the direction of approximating the bowed members. In order to prevent the patient from easing the strain by raising her knees the legs were bound down to the wooden platform. The apparatus, as might have been expected, produced a certain amount of cramp, but she was able to bear it quite 16 hours out of the 24.

Meanwhile the patient was given cod-liver oil, phosphorus, and virol; later she had the iodide of iron, and finally thyroid extract. Altogether, I treated her for nine months, two-thirds of which time she lay on her back. The results were disappointing. By the end of six months the legs had grown half an inch in length, and the knees came one and three-quarter inches nearer together; but it is questionable whether this slight improvement was due to anything other than the weight being taken off them. At any rate, an attempt to resume walking produced a rapid recurrence. All I could suggest now was a double osteotomy, followed by at least a year on a couch. Her people demurred to this, however, and I did not press them. Shortly afterwards they left the neighbourhood and I lost sight of the case.

To my mind the relationship between such cases as the above and infantile rickets appears more than doubtful. The rickets of early childhood is now generally admitted to be a disease of nutrition, and is readily amenable to suitable Journal, 1888, p. 357.

dietetic measures. That this girl, the daughter of well-to-do country people, suffered from improper feeding is hardly probable. Mr. Clutton's patient was likewise of respectable parentage. I note, too, in his account the same absence of early rachitic history, the same resistance to treatment. Is it not better to admit frankly that we do not know the etiology of the affection? The most we can say is that the disease appears to be connected with the development of the sexual functions; and that, as in the case of those bony and arthritic lesions which occur during pregnancy and the menopause, it may be in some obscure way associated with changes in the internal secretions of the generative glands.

Cockton Hill, Bishop Auckland.

A CALCIFIED LEFT OVARIAN DERMOID. SEPARATED FROM ITS PEDICLE. TRANSPLANTED

ON TO THE RIGHT BROAD LIGAMENT AND VESICAL PERI-TONEUM; REMOVAL ON THE TENTH DAY OF THE PUERPERIUM FROM A 12-PARA.

BY FRANCES IVENS, M.B., M.S. LOND.,

HONORARY MEDICAL OFFICER FOR THE DISEASES OF WOMEN, LIVER-POOL STANLEY HOSPITAL.

INSTANCES of transplanted ovarian tumours were more often recorded by the early ovariotomists when operative measures were not readily undertaken and long-standing cases more frequently came under notice. Sir Spencer Wells refers to a case described by Dr. Atlee, who found a dermoid tumour post mortem in a woman aged 79 years. The presence of a tumour had been recognised 47 years before by Dr. Atlee's uncle. There was no pedicle, and the tumour was dependent upon adhesions for its vascular supply. Sir Spencer Wells himself operated upon a case where the tumour had been present 18 years. During that time the patient had married and had had three children, the tumour lessening with the progress of each pregnancy. There was no pedicle, the blood-supply having been kept up through the vessels of adhering omentum and mesentery. The patient was pregnant at the time and was delivered of a living child seven months after. Mr. Alban Doran 2 described a case he witnessed which was operated upon by Mr. Knowsley Thornton in 1881. A woman, aged 34 years, had for seven years presented symptoms of an abdominal tumour, and in the interval had given birth to four children. A spherical dermoid cyst of the size of a cricket-ball was removed. It was entirely detached from its pedicle and adherent to the omentum. The right ovary was cystic and was removed. The left Fallopian tube was obstructed and slightly dilated; close to it in the site of the ovarian ligament lay a short firm tag of fatty and partly calcareous tissue. In a paper on Twisted Pedicles Mr. Knowsley Thornton mentioned four instances of ovarian dermoids where the pedicle had completely separated.

Transplantation of ovarian tumours is probably usually preceded by torsion and gradual attenuation of the pedicle. As torsion occurs more frequently during pregnancy and the puerperium it is not remarkable that most of the recorded cases have occurred in multiparæ. The length of the pedicle and amount of play allowed are important factors, any drag after the twist has started being sufficient to cause the pedicle to give way. The tumour, usually an aseptic foreign body, transplants itself on to the nearest omentum or intestine. When sudden torsion takes place acute symptoms immediately arise resembling those of intestinal obstruction, and rupture of the tumour from hæmorrhage into its cavity or necrosis or suppuration may occur. If the twist is gradual there may be little to mark the event. Congestion of the tumour may be followed by atrophy. The nutrition is impaired, but adhesions may gradually form and augment the blood-supply. Fibrosis and calcification may follow.

The atropied pedicle may rupture, and if the tumour is free it may find a new resting place in the abdominal cavity, plastic adhesions forming between it and the peritoneum, and providing a new blood-supply.

 Doran: Tumours of the Ovary, London, 1884, p. 118.
 Knowsley Thornton: Rotation of Ovarian Tumours, International

The following case is that of a woman, aged 40 years, and married 22 years, who was sent up to the Stanley Hospital by Dr. Gertrude M. Hutton as a case of pregnancy complicated by a tumour. The patient stated that she had married at 18 years and had had 11 children. Her first child was born without difficulty at seven months in 1887, her health during pregnancy having been good. She had a quick confinement and was attended by a medical man. In 1890, when four months pregnant, an attack of inflammation occurred, and the medical man who attended her thought she had a displacement. In 1891 a seven months' child was born after very bad health during pregnancy. With the fourth she was better, but severe "inflammation" occurred after the fifth, sixth, seventh, and eighth confinements, when she was attended by midwives. During the ninth pregnancy fainting attacks occurred, coming on generally when she was on her hands and knees scrubbing. With the tenth child she had the same poor health and trouble with micturition. In 1906, after the eleventh confinement, she recovered strength very slowly, and the periods were absent 14 months. On June 10th, 1908, amenorrhœa began and lasted until Sept. 4th, when hæmorrhage occurred, lasting until the end of the month. The patient then noticed that the pain, which hitherto had been on the left side, now occurred on the right side and in separate attacks. A short time later she became aware of the presence of a tumour on the right side. On this account she sought advice in November at the Dispensary for Women, and was sent on to the Stanley Hospital the same week. The patient was then about five months pregnant. A hard mass of the size of a feetal head could be seen and felt in the right iliac fossa. Though not very moveable it could be pushed down partly into the pelvis and did not appear to be in close connexion with the enlarged nterus. Pressure caused severe pain. The diagnosis was uncertain, but the situation and consistency were rather in favour of a subperitoneal fibroid.

As the pain increased the patient was admitted on Jan. 3rd, when seven months pregnant. The temperature and the pulse were normal. The swelling was very obvious and gave the abdomen the appearance of a transverse presentation. After a few days' rest in bed the pain subsided and the patient was sent home with instructions to come up at the This she did on Feb. 1st. The house onset of labour. surgeon, Mr. M. Greer, reported that it was a posterior wertex presentation. Labour was unusually prolonged, although it was an eight months child, and the head showed considerable moulding. There was no excessive post-partum hæmorrhage. A hard mass could still be felt in the abdomen in front of, and quite distinct from, the uterus. The question of ovarian tumour was considered. The child showed little vitality and died in 24 On the third day the patient's temperature ran up to 102° F., but quickly fell to normal. As the patient went on well and the uterus involuted I did not operate until Feb. 13th. The omentum was spread out over a tumour of the size of a feetal head extending from the right iliac fossa towards the pelvis. On dividing the omentum deeper adhesions were apparent between the tumour, the vermiform appendix, and the right tube. The tumour was fixed by a broad base on to the anterior surface of the right broad ligament and peritoneal surface of the bladder. adhesions were ligatured and divided. A large aperture in the right broad ligament was closed with a continuous catgut suture. A stump consisting of about three-quarters of an inch of the left tube remained attached to the uterus, the free end impervious. A scar indicated the former position of the left ovary, the infundibulo-pelvic ligament, and the ovarian ligament. The right tube and ovary were normal. The patient made a good recovery and left the hospital on the twelfth day after operation. She now looks well and is free from pain.

The tumour measures three and a half inches in diameter and is, roughly, circular in shape. Adhering to its surface can be seen the remains of omental and peritoneal adhesions. Microscopically, sections show the lining to be of squamous epithelium. The wall is densely fibrous, with areas of calcification. The contents resemble mortar, mixed with hair and oil.

In this case there is no history of acute symptoms to mark sudden axial rotation of the tumour. The pedicle may have begun to twist during the early months of the second pregnancy, for there is abundant evidence in the tumour that its blood-supply has been deficient for many

years. Had it then become fixed in its final situation it could hardly have escaped the attention of medical men, midwives, or the patient herself for so many years. Complete separation probably took place in the third month of the last pregnancy, when, after hæmorrhage for some weeks, the pain changed its locality and the tumour was first noticed. It was now in a situation to cause a certain amount of obstruction and it is interesting that this was the only lingering confinement.

Abortion is believed to be common in cases of pregnancy associated with ovarian tumours, and this patient had several premature births. It is somewhat remarkable that in spite of the alleged mortality of 25 per cent. of untreated cases of ovarian tumour complicating pregnancy this patient escaped with her life through 12 confinements in 20 years. The expectant treatment of this case was based on a diagnosis of subperitoneal fibroid, and the patient was admitted to hospital with a view to operative treatment should serious obstruction to delivery occur. Had a diagnosis of ovarian tumour been made its removal during pregnancy would have been a matter of great difficulty on account of the very extensive adhesions.

Liverpool.

A CASE OF OBLITERATIVE ARTERITIS.

BY R. ALLAN BENNETT, M.B. LOND., HONORARY MEDICAL OFFICER IN CHARGE OF ELECTRICAL DEPARTMENT TORBAY HOSPITAL, TORQUAY.

THE patient in this case is a woman, aged 52 years, who until 11 years ago had enjoyed fair general health. In October, 1898, she was seized, while resting quietly, by a sudden attack of pain over the heart, which lasted for some hours and departed as quickly as it came, leaving a sense of illness which has continued more or less ever since. The note of her previous history reads as follows: "Measles at 10 years. Nervous breakdown at 20. Was refused for insurance at 23. Miscarriage 7 years after marriage, and again 13 years later; slow recovery on both occasions." The family history was unimportant. As the patient describes it, she became conscious that she possessed a heart and blood-vessels, and only at rare intervals has she been free from the sensation. The feeling was most marked at night when she was quiet in bed, and she would lie, at one time listening to the heart beating loud and rapidly and to the blood coursing with a sense of power through her carotids, and at another, hearing it as though it were an exhausted clock, watching for every lingering pulsation, and wondering how many more there would be for her to count. Apart from the listlessness which accompanied the sensation of bodily illness, there was almost constantly a certain amount of pain, or at least discomfort, in the right arm, which could always be increased by slight exertion, and amounted sometimes to a degree beyond which the patient felt she could not go. With this there was a feeling of lifelessness and cold in the limb, and the skin over the back of the hand was often discoloured in a patchy manner, more especially when the pain in the limb reached its height. During the 11 years the disease had lasted there have been on several occasions acute attacks of illness, when the somewhat indefinite symptoms described have all been accentuated, and when pain in the chest (localised over the sternum and not spreading over the arm) has been constant and severe. During these periods the patient rested—now entirely and now in part, and always with the greatest benefit to herself. The pain and weakness experienced in the right arm have been felt, though to a less degree, in the right leg; the foot on this side is generally cold, and there is often a sense of insecurity when walking or even when standing quiet.

When first seen the patient looked ill and said that she was incapable of any exertion at all. The least movement brought on pain over the front of the chest and shortness of breath, and the right arm and hand became cold and livid, patches of bluish discolouration extending from the back of the hand up the arm. There was strong visible pulsation in the carotids, more marked on the right side, where the finger could feel a rough systolic purring thrill, which was absent on the left. On the left side, from a point below the

⁴ McKerron: Pregnancy, Labour, and Childbed with Ovarian Tumour, 1903. London.

middle of the clavicle, outwards a distance of 11 inches, there was visible pulsation, and the impression conveyed to the finger was that of a kinked vessel, which each systole attempted to straighten out. There was here also a systolic thrill, but softer and less insistent than that felt over the right carotid.

The cardiac dulness extended (a) upwards to the second space; (b) to the left, half an inch exterior to the nipple; and (o) to the right, a quarter of an inch beyond the right sternal margin and up to the third space. The apex beat was in the fifth space, half an inch external to the nipple line. On auscultation, the second sound over the apex was somewhat flapping in character, and the first was obscured by a rough murmur, which increased in intensity as it was traced up along the right edge of the sternum, until it attained its maximum strength just below the sternoclavicular joint. From this point it could be followed outwards along the lower edge of the clavicle, until at the junction of the outer and middle thirds of the bone it ceased abruptly. It could be followed upwards along the course of the carotid as high as the ear with very little loss of intensity. The murmur was rough and scraping and gave one the idea of considerable obstruction, with difficulty overcome. A fainter systolic murmur could be heard over the pulsating area below the left clavicle, audible also over the lower part of the left carotid, but it gave the impression of recency. It could be congave the impression of recency. It could be considerably increased by firm pressure with the stethoscope. The radial pulse on the right side could scarcely be felt and was delayed in time as compared with the other side. The artery appeared normal to the touch: the pulsation was no stronger in the axillary and the accessible portion of the subclavian than in the radial artery, and was delayed in time as compared with the other side. The blood pressure, measured by Riva Rocci's instrument, was 180 millimetres in the left radial and 130 in the right. On auscultation over the abdominal aorta a rough purring systolic murmur could be heard along its whole extent, and again from its bifurcation, on each side, over the course of the common iliac and external iliac into the femoral, where it was lost, disappearing at the apex of Scarpa's triangle. This murmur was louder in the right external iliac and femoral arteries than on the other side. In the right femoral artery the pulse was much weaker than in the left, and in the anterior tibial artery it could not be felt at all. The foot felt cold to the patient, though warm to the touch. It was not livid, and there was no pain in it or in any part of

The subsequent history shows slow improvement. patient rested entirely in bed for 3 months, and for 2 months more she only walked across the room to the couch, remaining there for the rest of the day. The pains in the chest have disappeared, but there is very frequent discomfort in the right arm and hand, amounting at times to severe burning pain. This is generally noticeable after exertion, but it may come on when the patient has been resting quietly. The same may be said of the variability of the pulse; sometimes, as on first examination, it can scarcely be felt, while at other times it is almost as strong as on the other side. The systolic murmur on the right side also varies in intensity and character, being at one time much more intense and powerful than at others; no relation, however, can be traced between the variations in the murmur and the pulse.

The pulsation in the area below the left clavicle at one time appeared to be growing more marked, and certainly the visible area was increased, pulsation being apparent to the eye also over a small area above the middle of the clavicle. The systolic murmur in this region became soft and blowing and gave the impression that some acute process was going on in the vessels where it arose, but these changes gradually died away until the condition now on the left side is much as it was when the patient was first seen. On examination with the X rays the screen showed plainly a marked uniform dilatation of the ascending arch of the aorta, but there was no sign of aneurysm. The urine was normal, about 60 ounces being the average daily excretion.

In giving a name to this condition none would appear more appropriate than "arteritis obliterans" had not this term, as far as my available literature goes, always been applied to disease of the smaller and medium-sized vessels only. Thus the originator of the name, Carl Friedländer, defines obliterative arteritis as a disease of the small and medium arteries,

characterised by a growth of connective tissue in the intima, and tending to gradual narrowing and eventual obliteration of the lumen; he says of this growth that it may remain for long as granulation tissue, or it may be transformed into firm fibrous tissue, which may completely obliterate the vessel; the tissue may contain relatively few cells, and it is noteworthy that fatty and calcareous degeneration seldom occur. Friedlander points out the analogy with the changes in the ductus arteriosus and the umbilical arteries, these changes being due, not to thrombosis, but to proliferation in the arterial walls; and he instances as examples of the same transformation the changes which occur in the lungs in phthisis, and also in fibroid tumours, sarcoma, elephantiasis, and cancer; where, however, thrombosis plays an equal or larger part in the process of obliteration.

The cases referred to by Pearce Gould, Spencer, Michels, and Parkes Weber, all appear to refer only to the disease as it affects the smaller vessels and emphasise the fact that it begins in the peripheral arteries and extends back-On the other hand, three cases described by wards. Hogerstedt and Nemser bear very close resemblance to the present one. In this communication the authors lay stress on the fact that the blocking of the larger arterial trunks may lead to little or no peripheral disturbance, and they instance the case reported by Mr. James Lane, where the patient suffered fracture of both collar bones and complete compression thrombosis of the right subclavian, the only peripheral effect being anæsthesia of the right little finger. They are inclined to attribute the condition in part to an endarteritis and in part to a slow thrombosis, and they draw attention to a combination of predisposing circumstances in a case reported by Heubner, where the patient, a blacksmith by trade, presented signs of complete occlusion of the right subclavian. In this case there were: (1) advanced arteriosclerosis; (2) a history of syphilis; and (3) laborious occupation. At the same time they do not lay it down that syphilis played the sole or even the chief part in the production of the disease, leaving it a doubtful question whether the endarteritis was a specific one or whether it merely arose in a person with the general constitutional taint. Hogerstedt and Nemser in speaking of the etiology of stenosis of the larger vessels springing from the aortic arch say: 1. Embolism has not been observed. 2. Sudden crushing or tearing of the vessels—e.g., in double clavicular fractures—is extremely rare. 3. The vessels may be constricted by the growth of mediastinal tumours (aneurysm most common) or by inflammatory processes. Aneurysm may also lead to occlusion of the lumen by extension of thrombosis or to distortion of the lumen by irregular alteration in the shape of the arterial arch. Much more frequent is thrombosis of the orifices of the vessels themselves; a condition rendered more likely by the presence of arterio-sclerosis, which generally occurs after the fortieth year of life, and when the disease in the aorta has gone as far as atheromatous degeneration. They point out that the subclavians are more liable to be attacked owing to the greater call made upon the circulation in the upper extremities.

I think that the condition present in this case is sufficiently rare to make its publication interesting. With the exception of the three examples described by Hogerstedt and Nemser, I can find no clear record of idiopathic stenosis of the great vessels springing from the aortic arch, and there seems to be little doubt that this is the state of things here. The patient has probably suffered from extensive disease of the arch, which has gradually involved, certainly the innominate artery, and probably the left subclavian as well. The carotids on both sides appear to be healthy, the loud murmur heard on the right side being simply conducted along the vessel. The signs in the left subclavian suggest the presence of acute disease, and whether this is to be followed by thrombosis with consequent narrowing of the vessel's lumen and a repetition in the left arm of the conditions obtaining in the right remains to be seen. The abdominal aorta, the external iliacs, and the femorals all appear to be affected by the disease and in the right femoral the disease appears more advanced than in the left. Signs already described as existing in the right leg can be explained by a diminution of the lumen of its main artery, and in all probability there is here a condition similar to that present in the right subclavian. There is not that variability in the pulse of the leg which is so noteworthy in the arm. I have never been able to satisfy

myself that there was any pulsation at all in the right dorsalis pedis.

With regard to treatment there is not much to be said: rest and potassium iodide in increasing doses appear to be doing a considerable amount of good, but it is an open question whether the improvement will continue when the patient resumes a more active life and moves about again.

Torquay.

THE IMPORTANCE OF THE EARLY RECOGNITION OF TUBERCULOUS MEDIASTINAL GLANDS IN CHILDREN.

BY JOHN ALLAN, M.D. EDIN., D.P.H.

In the study of latent pulmonary tuberculosis in children we are confronted with a difficult problem, and many points have to be carefully considered in our endeavours to deal correctly with it. On examining the subject the question naturally arises, "Should tuberculosis of the bronchial or mediastinal glands be included under the term pulmonary " I think there is no doubt that it should be, because in many instances the glands are primarily affected, the lung condition being secondary, but the difficulty is how is it to be diagnosed. In many instances the diagnosis of tuberculous mediastinal glands is purely hypothetical, but post-mortem evidence indicates that the condition is by no means uncommon, and that it may occur in children in whom it was not even suspected. Dr. Theodore Shennan 1 at the International Congress on Tuberculosis at Washington last year gave an interesting analysis of 1085 postmortem examinations which had been carried out at the Edinburgh Royal Hospital for Sick Children during the last 21 years. 421 of these, or 38 8 per cent., were on children who had died from tuberculosis. He found that tuberculosis of the mediastinal glands was commonly unaccompanied by primary tuberculosis of the lungs, but was frequently accompanied by recent tuberculosis of these organs, in many cases secondary to gland tuberculosis. It is important, therefore, that every endeavour should be made to diagnose this condition, so that by appropriate treatment the progress of the disease might be checked or cured. Dr. C. Leroux² believes that chronic pulmonary tuberculosis in children has two modes of origin: (1) glandular, which begins clinically in the tracheo-bronchial glands and after a longer or shorter time reaches the apex of the lung; and (2) pulmonary, which begins first in the apex of the lung and is accompanied secondarily by disease in the glands. The former generally occurs in young children under 10 years of age, while the latter is most common between the ages of 12 and 15. One should therefore make every effort to diagnose glandular infection, as in view of the long truce which exists before the gland affection reaches the lung and the energetic defence which in young children is opposed to its extension there is every chance of the disease being eradicated by suitable treatment. Gland affection should be especially looked for in children at or shortly after the commencement of their school life. The question at the present time becomes all the more urgent since, with the development of the medical inspection of school children, there will be greater opportunities for the examination of children; and it is to be hoped that any suspicious cases will be picked out and referred to the family medical attendant for fuller investigation. It seems probable that quite an appreciable percentage of the present wastage of useful lives might be prevented if these cases were early recognised.

The general symptoms of tuberculosis must be carefully analysed when we come to consider the diagnosis of tuberculous mediastinal glands, and one may expect to find the usual symptoms of wasting, anorexia, accompanied, perhaps, by irregular pyrexia. The symptoms suggestive of tuberculosis in children are legion, and unfortunately there is no symptom which can be relied on to indicate that the child is phthisical. My own experience has been that afternoon fever, shown by flushed face and tired feeling, is fairly significant of tuberculosis. In all cases of tuberculosis in children which have come under my notice, and in which there was no doubt regarding the diagnosis, this symptom was well marked. Another important symptom is anæmia. In non-tuberculous conditions in which there are symptoms suggesting tuberculosis there may be pallor, but marked anæmia in an emaciated child is, as a rule, only met with in a phthisical subject, provided, of course, the different varieties of anæmia of childhood can be excluded. Loss of weight is undoubtedly a symptom of the tuberculous, but it is also a symptom of many other conditions. To be of any use the record of the child's weight over some months must be studied, and any child suspected of being consumptive ought to be regularly weighed. A child who is being treated as tnberculous and whose weight steadily falls or even remains stationary may be regarded as in all probability the subject of phthisis. In no other chronic lung condition (except in very exceptional cases) will weight fail to increase with treatment. Night sweating, dyspepsia, anorexia, &c., are other symptoms, but all that can be said is that they may afford confirmatory evidence, and in the majority of cases they are due to conditions which are non-tuberculous.

Passing on, we come next to the symptoms and signs more especially associated with the particular variety of tuber-culosis at present under discussion. Perhaps the most valuable local symptom is the presence of a spasmodic cough. This cough consists of a number of sharp, short expiratory efforts followed by a long-drawn inspiration. The cough is very similar to that met with in whooping-cough and may easily mislead the uninitiated. A history of a previous attack of whooping-cough will tend to exclude that disease and will favour the diagnosis of enlarged bronchial glands, because a second attack of whooping-cough in the child is rare. Again, if this spasmodic cough persists after an attack of whoopingcough it is wise to suspect that its continuance may be the result of enlarged bronchial glands. The only other condition which is likely to give rise to a similar cough is bronchiectasis, but this is not often met with in children. The signs of cavity formation and the copious intermittent and feetid expectoration should be sufficient to establish a diagnosis. Except in old-standing and advanced bronchiectasis there is not the same emaciation nor anæmia that there is in tuberculosis. In early enlargement of the bronchial glands physical signs are absent, but one has only to remember that these glands are small and deeply situated in the mediastinum, and this apparent anomaly is explained. However, there may be on percussion dulness behind the manubrium sterni. This dulness, according to Dr. Robert Hutchison, sextends outwards towards the apices of the lungs and downwards towards the heart. If the enlarged gland causes constriction of the main bronchus quite a definite train of physical signs may be detected. One of the earliest signs of constriction of a main bronchus is diminution of vocal fremitus. Later the vocal resonance is impaired, the breath sounds are feeble, and the chest expansion is defective. If the pressure is sufficient to prevent the entrance of air or if one of these large tubes has been plugged by a caseous mass there is an absence of respiratory murmur over a single lobe or over an entire lung. Dr. L. Emmett Holt considers that this sign is of great diagnostic value, but it is not often present. Dr. R. A. Young, while admitting that there may be weak breathing over the whole of one lobe, mentions that even in these cases it is well to remember the functional irregularity of the diaphragmatic movement in children, which can be readily observed with the X rays, and to examine the chest on several occasions to see if the alteration is a permanent one. Grancher's sign is very variable and cannot be relied on. This is a permanent alteration of inspiration at one apex, and was considered by

See THE LANCET, Jan. 30th, 1909, p. 315.

 Brit. Med. Jour., March 7th, 1908.

Grancher to be quite sufficient to indicate this condition. He describes three stages in this alteration-namely, weakening of inspiration, and later bronchial breathing with bronchophony. The phenomenon is essentially an asymmetry of inspiration. D'Espine ⁶ states that in the normal child bronchophony ceases at the level of the spine of the seventh cervical vertebra, while in these cases it may be heard down to the level of the fourth or fifth dorsal spine. Other two signs may be mentioned—namely, distension of the veins of the neck and Eustace Smith's bruit. The former is caused by pressure of the bronchial glands on the superior vena cava, while the bruit is heard in the veins on placing the stethoscope over the manubrium sterni. Dr. Smith points out that the bruit is best heard when the child bends back its head. The signs are generally only present when the glands are much enlarged, and it is by no means uncommon to find post mortem considerable enlargement of these glands without there having been any physical signs during life. In the opinion of Dr. Young the coexistence of several of these signs, especially if one of them be dulness in the interscapular region with a positive tuberculin reaction, renders the diagnosis highly probable.

In the investigation of any case of a child supposed to be consumptive it is most important to take into account the family history as regards tuberculosis and also the history of definite exposure to infection. It is the fashion in some quarters to ridicule the idea of heredity playing any part in the tuberculosis problem. Even if the transmission of tuberculosis from parent to child be not admitted, surely it may be said that the child of a tuberculous stock will have a predisposition to the disease. It is doubtless true that the child is infected from some other person who has phthisis, or through the medium of milk, &c.; but to exclude all possibility of hereditary taint is incorrect. Dr. T. N. Kelynack 7 evidently holds this opinion, for he writes: "While, however, the tuberculous seed is quite exceptionally transmitted from parent to child, a tuberculously disposed soil is undoubtedly inherited." If there has been phthisis in the family then the child will almost certainly be more liable in adverse circumstances to contract the disease on exposure to infection than a child whose family history sheet is unmarred by the presence of pulmonary tuberculosis. If two children of the same age were taken, the one having a family history of consumption, the other having no such history, and if these children became exposed under as nearly similar conditions as possible to infection by tubercle bacilli, then surely the child who had the increased premium of tuberculous taint on his life would be the first to contract the disease. Other things being equal, the child with a tuberculous family history requires careful medical supervision, and any suspicious symptoms in such circumstances should not be regarded too lightly.

We can make use of several diagnostic aids in the elucida-tion of the case. For instance, the subcutaneous injection of tuberculin controlled by the opsonic index estimation is a diagnostic agent of much value. Unfortunately the elaborate technique required militates against its more general employment. The ophthalmo-reaction of Calmette and von Pirquet's cutaneous reaction are useful and the general opinion is that they are reliable. The former appears to be the more reliable, but a number of cases have been placed on record where serious inflammatory mischief has occurred in the eye as a result of the application of Calmette's test. blood may be examined for eosinophile cells, which are said to be absent in early tuberculosis. Dr. R. C. Rosenberger has recently demonstrated the presence of tubercle bacilli in the blood of the tuberculous, and he believes that they appear in this medium at a very early period. An X ray examination should never be omitted. Dr. David Lawson, Dr. C. W. Cunnington, 10 and others have testified to their value, though such a high authority as Professor A. Calmette 11 believes that they reveal only old lesions. Cunnington points out that in the "right oblique" position we get an excellent view of the posterior mediastinum, which appears as a triangular light space, bounded by the heart in front and above, the aorta and spine behind, and the

diaphragm below. This area in health is clear and becomes markedly luminous on deep inspiration. When the retrocardiac glands are enlarged the space remains dark. This phenomenon occurs very often in sickly anæmic children, and we cannot be surprised when, only too often, such children ultimately fall victims to consumption. They are described as having a "tendency to consumption." The X rays tell us that in reality they already carry the germs of the disease within them. Cunnington thinks that with this diagnostic weapon a patient should no longer be labelled "Query early consumption?" and he very pertinently remarks that we must look for the answer by the light of the X rays, remembering that "coming events cast their shadows before." The chest should not only be examined by the fluorescent screen, but should also be photographed. By the former method the movement of the diaphragm and any area of shadow can be studied. By means of the photograph we obtain impressions of very small areas of disease, too small to show on screen examination.

From the above brief consideration of this important subject it will be clearly understood that the diagnosis is a matter of great difficulty, but the value of the early recognition of tuberculous bronchial glands can hardly be over-estimated. All children who are "physiologically delicate" should be suspected of being phthisical, and every method at our disposal should be employed to assist in coming to a positive decision regarding the case.

Edinburgh.

A CASE OF CARCINOMA OF THE VERMI-FORM APPENDIX.1

BY ALEX. MILLS KENNEDY, M.B., CH.B. GLASG., ASSISTANT PATHOLOGIST TO THE GLASGOW ROYAL INFIRMARY; PATHO-LOGIST TO THE GLASGOW MATERNITY AND WOMEN'S HOSPITAL.

In the routine histological examination of appendices removed at operation it is not uncommon to find the lumen narrowed or occluded by strictures the result, as a rule, of post-ulcerative cicatrisation. Sometimes these strictures are only detected when longitudinal sections of the organ are examined microscopically, there being no external evidence such as diminution of the circumference of the appendix at the seat of the occlusion; but occasionally the stricture is apparent externally by a deep constriction. Usually the appendix becomes distended beyond the stricture and various pathological changes take place therein. In the present case there is not merely a constriction but the appendix is completely divided into two segments, and in the sequestrated distal portion there is present an unmistakable carcinoma.

Carcinoma of the appendix is a condition which has been recognised for a considerable time, but as regards the earlier cases there is some doubt, owing to the want of any histological examination and also to the fact that in some it was quite possible that the disease was secondary. However, now that it is customary to have all appendices removed at operation submitted to microscopical examination, the cases reported have become more numerous and their nature has been placed beyond doubt. An excellent summary of the literature and cases on record until 1906 was given by Rolleston and Jones in their paper on Primary Malignant Disease of the Vermiform Appendix, read before the Royal Medical and Chirurgical Society in February, 1906, from which the following list of cases has been taken. The first case of malignant disease of the appendix was reported by Merling in 1838; the next case (Prus) was reported in 1865; and two years later four cases of carcinoma were reported by Rokitansky. All of these cases, however, must be considered doubtful owing to the absence of histological examinations. The next case of carcinoma was recorded in 1875 by Kolaczek, but here the tumour involved the cacum also, and it is possible that this was its primary seat. In 1880 Bierhoff reported a case, but in this instance there was tumour in the rectum and other organs, so that we cannot exclude the appendicular growth from being secondary. In 1882 the first undoubted case was recorded by Beger. In 1883 another case was reported by Maydl, but no details are given.

¹ Sections of the appendix were shown at the Pathological Society of Great Britain and Ireland at their meeting held at Glasgow on July 9th and 10th, 1909.

In Draper's case in 1884 the cæcum was involved, and so it also must be considered doubtful. The next case was recorded in 1896 by Stimson. In the following year 4 cases were reported, but one of these is rather doubtful. In 1898 another case (Wright's) was recorded, whilst there were reported 8 cases in 1900, 4 cases in 1901 (one of which is doubtful), 3 cases in 1902, 3 cases in 1903, 2 cases in 1904, and 4 cases in 1905, all of these being probably true primary carcinomata of the appendix. Apparently the condition has never been diagnosed before operation or postmortem examination, and this is not suprising, because in the great majority of cases the symptoms have been those only of appendicitis.

The patient from whom the present specimen was obtained is a man, 49 years of age, who until recently had enjoyed good health. The first illness occurred three years ago, when he was confined to bed for 14 days with an attack resembling influenza. In January, 1909, he was seized with a similar influenzal attack, characterised by shivering and backache. He had to go to bed, where he remained for two weeks, and, improving greatly, three weeks later he was able to resume work. But from about this time he continued to lose flesh. About three weeks before admission to hospital he was seized with a similar attack, with fever (at onset only) and vomiting. His medical attendant on this occasion suspected the appendix region, and found there was tenderness

on pressure at this place.

The patient was seen by Dr. T. K. Monro in consultation on May 4th, 1909. He had been obviously losing strength considerably; there were progressive failure of health and weakness, with considerable loss of flesh; and, taking everything into consideration, Dr. Monro came to the conclusion that these were incompatible with the condition being one of simple appendicitis. He had a suspicion that the patient was suffering from some malignant disease in the appendix region, not necessarily in the appendix because of its great rarity, but probably in the cæcum. For these reasons Dr. Monro advised his removal to hospital for observation. He was admitted to Dr. Monro's wards at the Royal Infirmary here on May 11th. On the 13th he was transferred to Mr. H. Rutherfurd's wards for exploratory operation. When

ploratory operation. When examined on the 18th by Mr. Rutherfurd before operation the only suggestion of appendicitis was the persisting tenderness in the right iliac fossa. Pain had quite gone, and there was no recognisable tumour. The abdomen was opened in the usual way. The appendix was rather bulbous and hard, adherent, running inwards and partly buried in adhesions of the small bowel and mesentery. About it, when separated, was seen some whitish material like the incompletely absorbed remains of an abscess. The appendix was cut away, and the stump was inverted in the usual way. The wound healed by primary union, and the patient was dismissed well on June 5th, and has since remained well. Mr. Rutherfurd states that at the operation there was nothing found which in any way suggested to him that there was any malignant disease present in the appendix, cæcum, or the neighbourhood.

The appendix was sent to the Pathological Department of the Glasgow Royal Infirmary for examination after it had been fixed in formalin and preserved in spirit. It was shorter and thicker than the normal, and it was completely divided, transversely about its middle, into two distinct segments, proximal and distal, which were held together only by the meso-appendix. The two segments were almost equal in length, but the proximal was slightly the longer of the two. For purposes of examination the appendix was divided in its long axis; one-half, consisting of the two segments, was

embedded in paraffin and cut into longitudinal sections. Transverse sections were also prepared from the distal segment of the other half.

Microscopical examination of longitudinal sections.—Proximal segment.—All round the appendix in the peritoneal coat there is evidence of recent inflammation. The meso-appendix shows marked evidence also of fairly recent inflammation—there is abundant lymphocytic exudation; the adjoining muscular coat of the appendix is also superficially infiltrated with these round cells. The muscular coat shows some fibrosis, and there is thickening of the submucous fibrous layer, probably the result of some former acute attack. The mucous membrane shows an overcrowding with lymphocytes, but there is no evidence of acute inflammation; the mucous membrane is fairly well preserved. There is not the slightest trace of carcinoma in this segment.

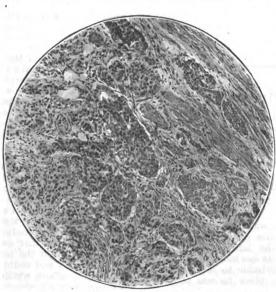

Distal segment.—Externally this segment also shows signs of recent inflammation. There is no lumen; the mucous membrane is altogether lost, and its place and the cavity are occupied by a characteristic carcinoma. The muscular walls are thickened and fibrosed, and just at the tip of the appendix the submucous layer is seen to be replaced by fat. At the distal end of this segment, within this submucous layer and replacing the mucous membrane, there is seen the carcinoma arranged in large masses in the alveoli of a firm but scanty fibrous stroma, and filling up the whole lumen.

Around the tip the wall of

Around the tip the wall of the appendix is not involved by the growth. From the distal end the growth extends proximally right to the division between the two segments but no further. It spreads laterally through the walls of the appendix to the peritoneal surface, and it is quite possible that it has extended by continuity into the surrounding adhesions.

The cells are columnar; they are arranged in alveoli and form in most places solid masses of cells, no trace of a lumen being visible. In some parts the cells are seen several layers deep surrounding a small central space, in this way simulating tubules. Towards the tip of the appendix the alveoli are much larger than they are proximally, the masses of cells correspondingly being much larger. The fibrous stroma is rather scanty near the tip, but proximally it is more

tip, but proximally it is more abundant and denser, and the tumour here has a resemblance to a scirrhous carcinoma. In the centre of what was once the lumen of the appendix the alveolar arrangement of the cells is fairly well preserved, but peripherally the normal limits of the tubular growth are broken, and cell-processes are seen extending out in all directions. At and around the tip of the appendix the carcinoma is limited within the submucous layer and does not send out processes into the muscular wall; but proximally, from within a short distance of the it is seen to break through the submucous coat and to sprout out into the muscular coats. These processes are composed of solid masses of cells not quite so tall as the cells in the central part of the tumour, approaching more to a spheroidal form, and they are seen infiltrating the muscular coats right up to the peritoneal surface. The infiltration in the muscular wall looks like a lymphatic permeation, the cell-processes in places being seen passing through between some of the muscular fibres, in the hiatus musculares described by C. B. Lockwood. The microphotograph is taken from a transverse section near the tip of the appendix and is magnified 75 times. It shows the large cell masses of that situation arranged in the alveoli of the rather scanty fibrous stroma. In a few of the smaller alveoli the tubular arrangement of the cells around a central lumen is apparent. The section also shows the carcinoma

Carcinoma of vermiform appendix. Transverse section at tip. \times 75.

invading the muscular wall, a solid process of cells being

There are one or two points of special interest in this case that are worth emphasising. While carcinoma of the appendix in itself is a rare condition, the situation of the special interest in the special interest in the special interest in the special interest in the special interest in the stranger is the special in itself is a rare condition, the situation of the special interest in t tion of the tumour in this case is quite unique. The appendix has been divided into two segments, in all probability the result of cicatrisation, and in sequestrated distal portion the carcinoma is situated. is of interest in view of Ribbert's theory of tumour formation-viz., that tumours arise from a partial or complete separation of cells or groups of cells from their organic continuity, in other words, from mechanical isolation. Although the condition has never been diagnosed, two cases in addition to the one reported above have been suspected beforehand. These two cases are mentioned by C. B. Lockwood in his article on appendicitis in Allbutt's "System of Medicine." In one instance cancer was suspected on account of the family history of cancer; and in the other on account of the marked anæmia, wasting, and loss of energy. This latter corresponds to the present case, in which there were obviously considerable loss of strength, progressive failure of health and weakness, in addition to the localising symptoms, all of which raised Dr. Monro's suspicions. In nearly every instance the symptoms have been those of one or other form of appendicitis, and as all medical men are now alive to the dangers of this condition and the advisability of early removal of the appendix, it is probable that to this is due the favourable prognosis in these cases. I am indebted to Dr. J. H. Teacher, Dr. Monro, and Mr. Rutherfurd for permission to publish this case. Glasgow.

MEDICAL, SURGICAL, OBSTETRICAL, AND THERAPEUTICAL.

FATAL CASE OF SEPTICÆMIA ILLUSTRATING AN IMPORTANT FACT WITH REGARD TO THE LYMPHATICS OF THE UPPER LIMB.

BY W. BARRIE BROWNLIE, M.B., CH.B. GLASG.

A FARM labourer, aged 25 years, was seen on May 22nd by my chief, Dr. O. N. Thomas. The patient was suffering from a painful swelling below the left clavicle. It had appeared two days before Dr. Thomas saw him. As the patient looked very ill it was thought advisable to remove him to the Lydney Hospital, to which place he was taken the same night. The temperature on admission was 100° F., and the pulse was 130. When I saw him on the following day I found that the infraclavicular fossa on the left side was filled up by a diffuse, hard, red swelling shading off into the surrounding skin. There was no fluctuation even on deep pressure. Considerable cedema was present, especially at the margins of the swelling. The shoulder-joint was quite free from pain on movement. There was no thickening of the clavicle, nor was any pain elicited when deep pressure was made over that bone. The axilla was quite free from glandular enlargement, and the inflammatory swelling had not invaded that region. Examination of the lungs showed nothing abnormal. The state of the pulse suggested that there was some severe microbic infection. There was a history of the man having had some inflammatory lesion which had gone on to suppuration round the nail of the left forefinger a fortnight ago, and although this had now quite healed up one could easily make out that there had been some acute inflammation in that region. As we could find no other point of infection we came to the conclusion that this was a case of acute lymphadenitis of the costocoracoid glands following on a paronychia of the left fore-finger. On the evening of the 23rd the patient seemed a little better, the pulse having somewhat subsided. On the 24th the pulse had again risen, this time to 140; the temperature still remained 100°. The swelling and cedema had now extended over the sternum to the right side of the chest, downwards to the nipple, and over the clavicle and shoulder. The same night the patient had a rigor, the temperature shooting up to 104°, and although no fluctuation could be

made out it was decided to open up the parts. The swelling was now covered with large vesicles filled with blood-stained serum. An incision about 3 inches in length was made in the interval between the pectoralis major and the deltoid muscles. Although a deep incision was made and the parts were opened freely by Hilton's method, no pus was found, only bloodstained serum coming away. Owing to the gangrenous condition of the parts, the muscles being swollen and flabby and the patient not feeling the incision, a bacteriological examination was made of the fluid which came away, but only streptococci were found. A large drainage-tube was inserted and the region was kept moist by a wet cyanide gauze dressing. On the next morning (the 25th) the patient had another rigor, and another swelling, of a similar nature to that on the chest, appeared on the right side of the neck behind the angle of the jaw. The nature of this was somewhat obscure; probably it was a thrombosis of the internal jugular vein. The pulse was scarcely perceptible and the patient died on the night of the 25th, the intellect being perfectly clear to the end.

In a general way we understand that an inflammation of the finger may spread to the glands of the axilla, although it is mentioned in some anatomical books that some of the lymphatics from the backs of the fingers may go along with the cephalic vein to the costo-coracoid group of glands in the infraclavicular fossa. This is a point which is not sufficiently emphasised, and several of these cases have been demonstrated to me, as a student, by Dr. Farquhar McRae of Glasgow. The lymphatics of the posterior aspect of the thumb, forefinger, and radial side of the middle finger frequently, though not invariably, with those of the radial side of the back of the forearm and back of the shoulder, go to the costo-coracoid glands, and this was the path of infection in this case. This state of affairs is perhaps more dangerous to the patient, as the costo-coracoid glands are nearer the great veins of the neck and also a step nearer the thoracic duct, as some of their efferent lymphatics empty directly into the subclavian vein (Quain). Perhaps one might argue that the paronychia of the left forefinger had not caused the blood-poisoning in this case, as that lesion had occurred a fortnight ago and the wound had quite healed up by the time the swelling on the front of the chest appeared; but we know well enough that organisms can lie quiescent in a gland until some slight injury may cause them to set up a severe inflammation. This seems to have been the sequence of events in this case, as the clear history of the paronychia a fortnight ago and the presence of a recent scar at the time of examination decided us in coming to no other conclusion.

I do not think that an earlier incision into the swelling would have saved the patient's life, as it was an inflammatory cedema and could scarcely be called an abscess, a condition of affairs which we would quite expect from an organism like the streptococcus The infection was of such a virulent nature that I do not think antistreptococcic serum would have done any good in this case.

Lydney, Gloucestershire.

A CASE OF TUBERCULOUS TESTICLE IN A CHILD AGED SIX MONTHS.

BY W. F. CHOLMELEY, F.R.C.S. ENG., HONORARY SURGEON TO THE WOLVERHAMPTON GENERAL HOSPITAL

On July 24th I was consulted about a child, aged six months, with a swollen, red, and very painful scrotum. The history given was that the swelling had been first noticed on the 19th and was supposed to have come on after an injury. On examination the scrotal tissues on the right side were found to be very inflamed and swollen but so painful that it was not possible to say if the testicle was affected. The child looked healthy and had been so since birth. The cord seemed to be slightly thickened. The child was admitted into the hospital and I ordered hot fomentations. The case improved very quickly, but on account of an outbreak of measles in the ward the child had to be sent out on July 28th before he was quite well. While outside the pain and swelling increased and became so bad that I had to admit the child again on August 4th.

The note made at that time is as follows: "The skin covering the left half of the scrotum is much reddened, and there is a large tender swelling occupying the natural position of the testicle, evidently an inflammatory enlargement of that organ. The cord feels thickened; the vas deferens cannot be felt. The temperature is normal." Thinking that it might be a case of torsion of the cord I decided to explore. On August 6th an incision was made in the inguinal region and the testicle in its thickened and distended tunica brought out into the wound. The layers over the tunica were much thickened and on opening it a quantity of turbid fluid escaped. The opening was enlarged and the epididymis was seen to be much enlarged and overlapped the body of the testicle. Under the globus major was a small collection of tuberculous-looking pus. I therefore removed the testicle. A section of the organ after removal showed numerous small caseating foci in the epididymis; the body of the testicle appeared to be healthy. Unfortunately, on August 11th the child developed measles and later broncho-pneumonia and died on August 19th.

A post-mortem examination was made and tubercle was found in the following organs: in some bronchial glands, in the left pleura, in both lungs, especially in the left, where there were some caseating foci, in the mesenteric glands, and in the left kidney, which was hardly developed at all. There was no tubercle found in the head or in the region of the bladder. Part of the testicle was sent to the Clinical Research Association and they reported as follows. "This testicle shows large inflammatory areas and a considerable degree of fibrosis. The inflammatory areas contain caseating foci and show some atypical giant cell systems. Although we cannot find any tubercle bacilli we feel sure the lesion is tuberculous."

ROYAL SOCIETY OF MEDICINE.

SURGICAL SECTION. President's Address.

A MEETING of this section was held on Oct. 13th, Mr. RICKMAN J. GODLEE, the President, being in the chair.

The PRESIDENT, in delivering his Address, said that prognosis in some of the common inflammatory diseases of the chest belonged at least as much to the physician as to the surgeon. The first and simplest condition was that of serous effusion into the pleura associated with acute pleurisy. They would all agree that patients who had had one attack of acute pleurisy with effusion and had been tapped once or twice, or not tapped at all, usually left the court without a stain upon their characters. They were admissible by insurance companies at normal rates, and the only record that remained (and that not always) was a slight departure from the normal physical signs, and perhaps of the mobility of the side that had been affected. The acute onset usually stamped their simple character. It was different when the onset was insidious. It had sometimes been suggested that most of the insidious cases were tuberculous. But it was no more true that they were all of that nature than it was that all the tuberculous effusions were insidious in their onset. He would expect an acute case to be caused by some septic organism and would be suspicious that a chronic one would turn out to be tuberculous even if no tubercle bacilli were found microscopically or by inoculation, with the mental reservation, however, that it might depend on a new growth. What was the outlook if a normal pleura was opened and drained? It had often been stated that an abscess of the liver might be safely opened through a normal pleura without any special precautions for closing the opening. This was not his experience. He had seen it followed by fatal results in septic cases or by very slow healing in amoebic ones. That was why he avoided injuring the pleura if possible and carefully closed the wound if it had been made. Were they justified, then, in incising and draining serous effusions that re-accumulated? To that different answers would be supplied. For himself, he was so afraid of leaving a permanently open pleura with collapsed lung that he advised repeated tapping, even up to seventy times seven, tedious though the process was. An effusion which was undoubtedly

tuberculous need not necessarily involve a very grave prognosis, one tapping being sometimes enough to effect a cure. Passing to the subject of empyema, he first offered some general remarks about the acute empyema of infancy. In 1886 he gave statistics when he was surgeon to the North-Eastern Hospital for Children and the average time for closure was six weeks. But that did not represent the usual course of things, three or four weeks was a common time for an acute empyema, and ten days or a fortnight was not rare, while a good number were cured by a single aspiration. The average was obtained by including the chronic cases. He did not gather that much better results were obtained now, although one might imagine that each successive writer on the subject had discovered some new panacea. A free opening, good drainage in the recumbent as well as the erect posture, the complete removal of all fibrinous masses, and the exercise of a wise judgment in removing the drainage-tubes were essential to success. The precise spot to half an inch at which the opening was made, the introduction or not of the gloved finger, and the presence or absence of an antiseptic material in the dressings were matters of less vital importance. soft chest walls of children and the elasticity of all their structures, and perhaps their more active vital power, seemed to favour the rapid closure of an empyema. Such cases were, he believed, common, almost typical, and he wished the medical officers of insurance companies would tell them something about them. They must apply for life insurance, and one would like to know whether any increased rate was imposed upon them. He should himself not advise it. He was afraid the particular answers desired were not to be obtained from insurance companies. It did not help them to know the average age of the patients insured (say in the Scottish Widows' Fund) who died from pleurisy and empyema, and it did not seem possible to obtain information as to the results from the point of view of the insurance companies of accepting proposals from those who had suffered from hydrothorax or empyema in childhood. Turning to acute empyemas in adults following acute pneumonia or pleurisy, the immediate prognosis as regards life depended upon the extent of the preceding disease and the amount of septic poisoning. The latter was indicated by the character of the pus; if that was sweet and only contained pneumococci the patients did not necessarily present what might be called an obviously septic appearance. If they did, and the pus was odourless it probably contained streptococci or staphylococci. If it stank there had probably been a rupture of a pulmonary or subdiaphragmatic abscess into the pleura. The pneumococcus cases if treated carefully antiseptically he thought did the best, especially if the lung was still somewhat solid from the pneumonia and the cavity was localised; but he had often seen (especially in hospital) a secondary pyrexia associated with a secondary septic infection. It was remarkable how well many of the stinking cases did. Some of the very worst septic ones might be snatched from death by continuous or repeated saline infusions or transfusions. Undoubtedly the great majority of those cases survived the operation, and he was not concerned with the small number who died within a few hours or days of it. An accurate prognosis as to the date of closure was impossible. Speaking generally, it might be said that the least favourable cases were those in which the cavity was large, or the lung was much collapsed, or the chest walls were very rigid, and those in which there was a very free communication with a bronchus. His own opinion was that those which were opened laterally were more likely to be slow in healing or to require a second opening than those which were incised posteriorly. So he thought that the prognosis was to some extent governed by the surgery. One would naturally expect that old people would do worse than young ones, but some healed remarkably quickly. Of the cases that healed the great majority remained well or had very slight inconveniences left behind. A small number had recurrences and some developed bronchiectasis. Although it was an undoubted fact that a small proportion of empyemata which burst into a bronchus recovered completely in the course of a few days or weeks, and that such a cure might be permanent (he had records of one case who remained well after 17 years), it might be stated that the majority of them required an external incision. But in most of those the fistula quickly closed and healing occurred as if there were
